AN interesting thesis on this subject is contributed by L. Brocq to the *Annales de Dermatologie et de Syphiligraphie*, July, 1915. He notes that the normal integument is not affected by any of the irritants of moderate intensity to which the majority of individuals are exposed. However, under certain circumstances the resisting power of the skin is diminished to such an extent that the skin is more or less affected by the same irritants. Such diminution may be general, local, or regional, and it may involve one or more of the elements of the skin. An illustration of generalized diminution of cutaneous resistance is seen in the case of a patient in whom the application of a substance such as a preparation of mercury to any part of the body gives rise to an irritation irrespective of the region of the body to which the application is made. Similarly in a case of congenital bullous epidermolysis slight traumatisms give rise to ulcers in whatever part of the body these traumatisms may be received. A localized diminution of cutaneous resistance is perceived in cases in which a definite area of the skin is exposed to a prolonged or repeated irritation, as in the various occupational diseases of the skin. Sometimes a single traumatism of sufficient intensity, as the action of a powerful physical or chemical agent, may modify the vitality of the skin exposed to this agent. The recognition of this fact is of extreme importance in dermatology.

The entire thickness of the skin may be affected, as in the xeroderma pigmentosum resulting from exposure to strong sunlight, and in the hydroa vacciniforme from a similar cause. The epidermis alone may be affected as in simple erythema. In some instances the cutaneous pigment is the only element that undergoes any change as the result of the action of the external irritant. The subject of cutaneous resistance is bound up with the special susceptibilities of the individual patient. Diminished resistance of the skin may be congenital or acquired, permanent or transient. The congenital type is seen in hereditary bullous epidermolysis, in congenital pemphigus with epidermic cysts, and in xeroderma pigmentosum. A number of the instances of urticaria, strophulus, and prurigo in infancy are probably to be attributed, at any rate in part, to a congenital diminution of cutaneous resistance. Among the cases of the acquired type there must be recognized those in which there are operative certain internal causes such as renal insufficiency, defects in oxidation, gastrointestinal fermentation, disturbances of the glands of internal secretion, etc. Changes in the nervous system may play an important rôle. Climatic influences are sometimes to be detected in the diminished resistance of the skin coexisting with the transient or permanent residence of an individual in a given locality.

Brocq emphasizes the fact that in studying the eruptions resulting from the action of external agents, one must distinguish between the traumatic factors *per se*, the cutaneous resistance of the individual, and the eruptions to which he is predisposed and which occur in the areas of diminished resistance. The types of the eruptions or their morbid aspects are independent of the degree of cutaneous resistance and of the external trauma. They depend upon the individual idiosyncrasy or upon the numerous internal causes acting at the moment. Thus an urticaria may be traced to the harmful action of certain ingesta; a papulo-vesicular eczema may result from renal insufficiency or intestinal fermentation; and a psoriasis may be caused by an excessive nitrogenous intake. These facts are of eminent significance from the therapeutic viewpoint. Above all it is necessary to caution the patient against further exposure to the external trauma which was originally responsible for the diminution in cutaneous resistance.

THE PITUITARY GLAND IN DIABETES MELLITUS AND OTHER ENDOCRINE DISORDERS.

DIABETES is nowadays regarded generally as a disorder of multiple etiology. It is a variable symptom-complex dependent upon disease of one or more of the organs of internal secretion. This conception has been based partly on clinical observation and partly on experimental investigation. Until recently the pancreas was the chief center of interest in the study of the problem of diabetes, but latterly attention has been shifted mainly to the pituitary gland. That the posterior lobe of this organ plays an important part in corbohydrate metabolism has been demonstrated by Goetsch, Cushing, and Jacobson; while the last two observers, in conjunction with Weed, have shown that electrical stimulation of the pituitary gland causes glycosuria even when this organ is severed from all nervous connection with the abdominal organs.

The next point of attack has been the study of the histological changes occurring in the pituitary gland in diabetes and in other disorders of the organs of internal secretion. This investigation has been carried out by H. J. B. Fry (*Quarterly Journal of Medicine*, July, 1915). The post-mortem material available for this research comprised eight cases of diabetes mellitus in which disease of the pancreas was also demonstrated, three cases of acute pancreatitis, one case of carcinoma of the pancreas, two cases of myxedema, one case of cystic

goiter, one case of Addison's disease, and two cases of hypertrophied thymus. The most important result of this study was the demonstration of definite histological changes in the anterior lobe of the pituitary body in cases of diabetes. These changes consist in the presence of adenomatous masses of eosinophile cells, colloid invasion of the anterior lobe, and areas of cellular degeneration. In cases of acute pancreatitis and carcinoma of the pancreas histological changes in the pituitary are absent or slight. In myxedema there occurs in the pituitary an increase in weight resulting from an increase in the connective-tissue elements and a hyperplasia of the chief cells. In goiter there is a hyperplasia of the chromophile cells, especially of the eosinophilic cells, and an increase of colloid material in the interglandular cleft. No histological changes were observed in the pituitary gland in the case of Addison's disease or in the case of status thymolymphaticus.

Fry presents a tentative explanation of the activity and mode of secretion of the pituitary gland. He states that the eosinophilic and basophilic cells are derived from the chief cells by the formation of zymogen granules. The granular cells represent a stage of active secretion, and glandular activity is greater toward the center and posterior border of the anterior lobe. From the granules is formed the colloid which is temporarily stored in the interglandular cleft and thence passes into the posterior lobe and infundibulum and gains access to the cerebrospinal fluid. The hyaline and granular bodies are derived from cells of the anterior lobe which have been carried into the substance of the posterior lobe in the process of development. It is upon these cells that the call for increased secretory activity first falls. Colloid in the interglandular cleft is then utilized, and if there is an overdemand upon the secretory activity of the anterior lobe, colloid may invade the posterior part of the latter and the cells themselves become rapidly converted into colloid, until finally areas of atrophy of the cells appear. The question is still undecided whether the posterior lobe activates the colloid in its passage, or adds some specific secretion of its own, or acts merely as an indifferent supporting structure.

Splenic Enlargement in Early Syphilis.

Relatively scant attention has been paid to this subject in the literature of syphilology. This is probably owing to the fact that early cases of syphilis do not come under hospital care and hence the opportunity of studying under ideal conditions the visceral changes during this stage of the disease does not frequently arise. U. J. Wile and J. A. Elliott (*American Journal of the Medical Sciences*, October, 1915) have made a study of this subject in one hundred cases of early syphilis. In thirty-six of these they found a definite splenic enlargement. The spleen was noted as being hard and firm in seventeen cases, as tender in six cases, and as very soft in three cases. The average enlargement extended about two finger-breadths below the costal margin. This type of hypertrophy is said to resemble closely in consistency that of chronic malaria. Under antisyphilitic treatment the enlargement disappears much more slowly than do the other early manifestations. This is comparable to the slow disappearance of the general adenitis. The splenic enlargement may be present before the secondary manifestations are apparent and is thought to represent the earliest syphilitic visceropathy. The enlargement is either in the form of a soft tumor not unlike that of any other infection or may present itself as a firm, tense tumor. In a small percentage of cases the enlarged spleen is tender and sometimes extremely so. The enlargement is most frequently noted in those cases in which the general health has been seriously involved. In 76 per cent. of those cases in which the spleen was enlarged there was a definite involvement of the central nervous system. In discussing the persistence of splenic enlargement the authors suggest that the spleen acts as a reservoir for the spirochetes or their "rest forms" and that the subsequent tertiary manifestations may possibly be due to reinfection of the blood stream from the spleen rather than to recurrences *in loco* from early dissemination—malaria being pointed to as providing an analogy in this respect.

Sclerema Neonatorum.

The first recorded case of this condition was that reported by Usembezius in 1718. For many years thereafter sclerema and edema neonatorum were confused with each other until Parrot in 1877 showed the clinical and pathological lines of demarcation between the two conditions. He erred, however, in regarding sclerema as one of the signs of athrepsia. W. S. Paterson (*Quarterly Journal of Medicine*, July, 1915) has made a careful study of two cases of sclerema neonatorum which he regards as a well-defined disease not necessarily associated with or secondary to any other recognizable morbid condition. It may vary considerably in degree as to the extent and severity of its manifestations and also as to the gravity of the prognosis. The differences between true and false sclerema are only those of degree. The disease is not as rare as is generally supposed, its most characteristic feature being a palpable subcutaneous induration with which may be associated abnormalities of temperature, most notably in the direction of its being subnormal. As complications there may occur visceral changes in the form of inflammations, hemorrhages, or serous exudations. There is probably no edematous type of sclerema, the edema being a complication rather than an essential feature. Microscopic examination of a well-marked case shows subcutaneous infiltration with small cells and increased fibrosis, with atrophy of the adipose tissue. These changes suggest that the origin of the disease is probably to be found in some microbic infection. The treatment must be largely symptomatic and should also be designed to combat the toxemia.

Cerebrospinal Meningitis in Switzerland.

The Swiss Republic has for many decades been known to harbor sporadic cases of cerebrospinal meningitis. Transmission is seldom observed and therefore isolation is never thought of. Individual predisposition is very slight and the meningococcus dies so rapidly that the presence of living carriers would call ordinarily for only a brief quarantine.

Naturally when there is cumulation of cases the situation is changed. At a session last summer of the Medical Society of Basle (*Deutsche medizinische Wochenschrift*, August 26) Staehelin reported three cases, two of which occurred in soldiers. Two patients died while the other seems to have survived. Very disconcerting were the negative finds of lumbar puncture. Diagnosis was certified in the fatal cases by autopsy. Cultures of the meningococcus were submitted. In discussion Wieland noted that the prognosis is very grave for nurslings, and also for adults, especially for soldiers. On the other hand, children of school age showed a truly remarkable resistance; not only is the case mortality low among these children, but the victims make clean recoveries.

Leprous Soldiers

To those who are familiar with leprosy in its early stages it will not seem strange to learn that leprous warriors are fighting side by side with their intact fellows. Eruptions, small excrescences, and anesthetic areas presented by a subject are not necessarily recognized as parts of one general malady, and taken singly could readily be confused with other conditions, especially such as result from war's hardships. At a session last June of the Royal Imperial Medical Society of Vienna (*Muenchener medizinische Wochenschrift*, July 6) Oppenheim showed a soldier with mixed leprosy. The eruptions on his face and limbs had been regarded as eczema, while the destructive lesions on his fingers were taken for results of freezing. The soldier declared that he had three brothers, all lepers, fighting in the ranks. The men came from Sarajevo, a region in which the disease is or was endemic. When he was examined by an expert the soldier's affection was at once seen to be leprosy, and the diagnosis was clinched by the discovery of Hansen's bacillus in the nasal secretions.

Sterilization of Drinking Water for Soldiers.

The drinking water encountered in military campaigns on foreign soil is almost always bad. An abundance of small filters may be taken along with gravel as filtering material, but German troops in Southwestern Africa found these impracticable because the breakage was heavy and the filters constantly became clogged. Boiling is an old and trustworthy resource, but instead of special outfits for boiling it is best to make an abundance of very weak tea or coffee, to serve as the sole beverage. This, however, is not adapted to hot weather, for the tea and coffee must be cooled somehow. Pasteurizing should be better for warm weather on this account. Ozone and ultraviolet rays serve well for sterilizing large vessels of water. Kruse, in the military supplement of the *Muenchener medizinische Wochenschrift*, August 24, after enumerating the above methods and resources, pronounces them all defective for wholesale use. We are, therefore, forced to draw upon chemical germicides. The best of these is probably chlorinated lime, 13 parts to 100,000, which in 10 minutes will destroy all life in the water. However, it now becomes necessary to remove the chlorine. This may be done by sulphites or peroxides. This problem is left to the large manufacturers who prepare two sets of tubes in a carton, one containing chlorinated lime and the other some harmless oxidizing substance.

News of the Week.

Dinner to Dr. Goldwater.—The retiring Health Commissioner was the guest of honor at a farewell dinner at the Hotel Savoy on November 6, given by members of the Department of Health.

The City's Health.—The report of the Department of Health for the year 1914, recently issued, shows that the general health of the city was improved and that the death rate was the lowest on record. There were 74,803 deaths reported, or 13.40 per 1,000 of the population, as compared with 73,902 deaths and a rate of 13.76 in 1913. If the 1913 death rate had prevailed in 1914 there would have been 2,010 more deaths recorded. Only three large cities in the United States showed a lower death rate than New York in 1914; Seattle, 8.11; Los Angeles, 11.27, and Cleveland, 12.72. Organic heart disease caused the largest number of deaths, pulmonary tuberculosis ranking next with a total of 8,918. The other chief causes of mortality in the order of their importance were: Lobar pneumonia, 5,145 deaths; chronic kidney diseases, 5,107; bronchial pneumonia, 4,533; cancer, 4,467; infantile diarrhea, 3,432; arteriosclerosis, 2,368; diphtheria and croup, 1,491; diabetes, 979; cirrhosis of the liver, 784; appendicitis, 710. The suicides during the year numbered 935, of whom 687 were men and 248 women, while of the total 304 were native-born Americans. During the year there were 140,647 births reported, or 25.19 per 1,000 population for the entire city, the rate in Manhattan, 25.77, being the highest, and that in Queens, 23.07, the lowest. In a study of the nativity of the parents of these children it was found that in 35,558 cases both parents were born in the United States, while in 80,872 cases both were foreign born. In order more effectually to protect the health of the public, the department has divided the city into districts which are regularly covered by inspectors from the Sanitary Bureau, and special investigations were made as to the conditions of stables, and of barber shops, and the sanitary precautions taken in the manufacture of butter and cheese. The appropriation of the Department of Health for 1914 was $3,534,240.50, and of this $3,363,767.85 was expended during the year.

Trace Obnoxious Fumes.—As a result of the recent investigation by the Department of Health the sources of the offensive odors emanating from the New Jersey shore of the Hudson have been traced, and representatives of the factories involved have agreed to do their best to abate the nuisance.

Personals.—Dr. Clarence A. McWilliams of New York sailed for France on November 3, to take charge of the French Military Hospital at Passy, which is to be supported by the French Hospital of New York.

Sir Wilfred T. Grenfell, medical missionary in Labrador, will shortly sail to join the Harvard unit of the Red Cross for active work in France.

Mr. Robert Bacon, ex-United States Ambassador to France, sailed on the *Rotterdam* on November 4, in connection with the work of the American Ambulance in Paris, and also of the Harvard surgical unit of the British Army. The Harvard unit is composed of thirty-two doctors and seventy-five nurses and will be in charge of a British military hospital of over a thousand beds.

Dr. John Hewat of North Adams, Mass., who was wounded recently while serving with the British Army in France, returned to New York on No-

vember 5, bearing the Distinguished Order Service conferred on him for bravery under fire.

Dr. WILLIAM J. MALONEY, professor of neurology at the Fordham Medical School, New York, who joined the surgical force of the British Army soon after the outbreak of the war, returned to this country on October 31 to recover from a wound received while under fire with the army on the Gallipoli Peninsula last June.

Dr. WILLIAM SEAMAN BAINBRIDGE recently returned from a visit to the front in France and Belgium. Dr. Bainbridge made an inspection of the hospitals and sanitary conditions in the war zone and also in Great Britain.

Dr. WILLIAM H. WELKER, assistant professor of physiological chemistry at the College of Medicine, University of Illinois, delivered the address at the opening of the college.

Dr. JOHN C. DONALDSON of the Johns Hopkins Medical School has been appointed instructor in anatomy at the University of Cincinnati. Dr. Edward F. Malone has been advanced to the position of associate professor of anatomy in the same university.

Dr. WESLEY M. BALDWIN, formerly assistant professor of anatomy in the Cornell University Medical College, has accepted an appointment as professor of anatomy at the Albany Medical College.

Dr. CHARLES V. MORRILL has been appointed instructor in anatomy, and Dr. Robert Chambers, assistant in anatomy, at the Cornell University Medical College.

The Fight Against Patent Medicines.—The Health Department of New York announced on November 4, the first conviction in the campaign being waged against medicines and appliances falsely advertised as cures. The manufacturer of "Holman's Ague, Liver, and Stomach Pads" having pleaded guilty in Special Sessions to the charge of misleading was fined $100.

Rockefeller Institute Wins.—The damage suit for $200,000 brought against the Rockefeller Institute for Medical Research and three members of its staff, by two of the former employees at the Institute, was dismissed in the United States District Court on November 4, because the facts stated were insufficient to constitute a cause of action. The plaintiffs in the case alleged that the doctors sued had persuaded them to submit to the injection of a serum and that as a result of carelessness and negligence they had become infected with an incurable disease.

Eugenic Ordinance Planned.—The health officials of Paterson, N. J., have under consideration the passage of an ordinance requiring that applicants for marriage licenses present certificates of fitness to marry. The arguments in favor of such a law are based upon a mass of statistics regarding children born in the city hospitals.

Mother of Nine in Eighteen Months.—Mrs. Drewry of Spencer Co., Ky., is reported to be the mother of nine children in eighteen months. Mrs. Drewry, who is about thirty years old, gave birth to five children in May, 1914, and on November 5, 1915, to four boys. Seven of the nine, all boys, have thus far survived.

Twilight Sleep Hospital.—The executive committee of the Twilight Sleep Association, at a meeting in New York on November 5, decided to establish a hospital where treatment by the Freiburg method could be given. A permanent finance committee was named, to undertake the task of organization, and it is expected that sufficient funds will be forthcoming. It is the belief of the association that the growing interest in the "twilight sleep" propaganda will be increased by the creation of a permanent center for both treatment and instruction for physicians from other parts of the country.

To Test Bottled Waters.—Commissioner of Health Emerson intends to insure the purity of bottled water sold in New York City by a thorough system of tests and a sanitary survey of the sources of supply. The Commissioner has denied the statement often made by the salesmen of bottled waters that the Croton supply is unfit to drink, and has declared that on the contrary the Croton water reaches the city in the highest state of potability. It is, moreover, analyzed daily by the Department of Health, so that any contamination would be quickly discovered, while other waters sold here have not previously been subjected to such tests.

Dr. Rowntree Appointed.—The Board of Regents of the University of Minnesota, St. Paul, has announced the appointment of Dr. Leonard G. Rowntree, assistant head of the department of medicine at Johns Hopkins University, to be professor of medicine and chief of the department in the University Medical School at Minneapolis.

Interned German Surgeon Dies.—Chief Surgeon Perrenon of the German cruiser *Kronprinz Wilhelm*, interned at the Norfolk, Va., Navy Yard, died there recently of heart disease after a short illness. Dr. Perrenon was a line officer in the German Navy with the rank of captain.

Win Pardon by Braving Disease.—Dr. Joseph Goldberger of the Public Health Service, who has been searching for the cause of pellagra, a disease which killed over 11,000 persons in Mississippi alone last year, has been helped in his experimental work by prisoners in the State prisons in Mississippi who have voluntarily submitted to the experiments. Out of eleven prisoners who were observed, six have developed the disease. The men have all been pardoned and will be released as soon as a course of treatment on the prison farm has put them into good shape.

Traffic Accidents.—The National Highway Protective Society reports that during the month of October 43 persons were killed by automobiles, 6 by trolley cars, and 4 by wagons in the streets of New York City. Twenty-seven of these were children under 17 years of age. This is an increase of 13 fatal accidents as compared with October, 1914.

Acid Fumes and Tuberculosis.—Dr. S. Adolphus Knopf of New York has recently addressed a letter to the health authorities in which he states his belief that the irritating fumes and obnoxious odors from certain chemical factories on the New Jersey side of the Hudson River are active factors in the spread of tuberculosis. He states that the odors cause many people to keep their windows closed at night and that the acid fumes aggravate the condition of those suffering from respiratory diseases.

New Cabinet Office.—The movement to create a new cabinet office to be known as the Department of Health, will be revived in the next Congress. The proposal is strongly supported by the medical societies, but is opposed by Christian Scientists and osteopaths as being in the interest of the "medical trust." The political parties, however, have declared for such legislation with the object of conserving public health.

New Cancer Hospital.—The new House of Calvary, a hospital for the cancerous poor of New

York, at Featherbed Lane and Macombs Road, the Bronx, was opened on October 31, when it was blessed by Cardinal Farley. The hospital was erected at a cost of $120,000 and is in the charge of the Sisters of St. Dominic. It was formerly located on Perry Street, Manhattan.

The Late Dr. Huddleston.—At a meeting of the Medical Board of Gouverneur Hospital, held November 3, the following resolutions were adopted:

Whereas, The Medical Board of Gouverneur Hospital has learned with the deepest sorrow of the death of its president and fellow member, Dr. John Henry Huddleston, visiting physician to the hospital for the past seventeen years, and,

Whereas, By the death of Dr. Huddleston the Medical Board has lost a warm friend and wise counsellor, and the hospital has been deprived of the services of one who was constantly planning ways and means for increasing the efficiency of the service, but it is in the Out Patient Department he will especially be missed. Here his great interest, his forceful appeals for help, and rigid discipline have not only resulted in building up a well-organized and efficient system for treating the out-door poor and the care of those suffering from tuberculosis in the vicinity of the hospital, but before his death he saw the beginning of a large, fine outpatient building, be it

Resolved, That the Medical Board extends to the members of the family of deceased its sincere sympathy in their bereavement, and be it further

Resolved, That these resolutions be spread on the minutes of the Medical Board and that copies be sent to the local medical press and a copy be sent to the family of the deceased.

HENRY MANN SILVER,
EDWARD WAITZFELDER,
Committee.

Obituary Notes.—Dr. SIGMUND TYNBERG of New York, a graduate of the College of Physicians and Surgeons, New York, in 1885, visiting physician to the Central and Neurological Hospital and the Workhouse and Penitentiary Hospitals, and a member of the American Medical Association, the New York State and County Medical Societies, the Greater New York Medical Association, the German Medical Society, the Metropolitan Medical Society, and the Eastern Medical Society, died at St. Luke's Hospital on November 3, aged 51 years.

Dr. HARVEY N. ABBOTT died of apoplexy at Philadelphia on October 25, at the age of 59 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1878.

Dr. WILLIAM GEORGE KIMBALL of Huntington, Mass., a graduate of the Dartmouth Medical College, Hanover, N. H., in 1876, and a member of the Massachusetts Medical Society and the Hampshire District Medical Society, died at his home, on October 20, aged 68 years.

Dr. LLOYD N. FRIZELL of Kansas City, Mo., a graduate of the University Medical College of Kansas City in 1896, died at his home, from Bright's disease, after a long illness, on October 18.

Dr. RICHARD H. MCBAINE of St. Louis, Mo., a graduate of the College of Physicians and Surgeons, New York, in 1907, and a member of the American Medical Association, the Missouri State Medical Association, and the St. Louis City Medical Society, died in Barnes Hospital, St. Louis, from blood poisoning, after a long illness, on October 17, aged 32 years.

Dr. HERBERT E. KNOWLTON, formerly of Cambridge, Mass., a graduate of Harvard University, Medical Department, Boston, in 1891, died at his home in San Diego, Cal., on October 24, aged 49 years.

Dr. FRANK HERBERT DANIELS of New York, a graduate of the Harvard University Medical School, Boston, in 1884, visiting physician to the Knickerbocker Hospital, for some years and a member of the American Medical Association, the New York State and County Medical Societies, the Society of Medical Jurisprudence, the Harvey Society, the Manhattan Medical Society, and the Greater New York Medical Association, died October 30.

Dr. JAMES H. WRIGHT of Newark, N. J., a graduate of the Georgetown University School of Medicine, Washington, in 1867, died at his home suddenly, on October 17.

Dr. ALEXANDER PERRY of Denver, Col., a graduate of Vanderbilt University, Medical Department, Nashville, Tenn., in 1905, and a member of the American Medical Association, and the Colorado State and Denver City and County Medical Societies, died in Los Angeles, Cal., after a long illness, on October 20, aged 34 years.

Obituary.

GEORGE MILLER STERNBERG, M.D., LL.D.

WASHINGTON, D. C.

BRIG.-GEN. GEORGE MILLER STERNBERG, U. S. A., former Surgeon General of the Army, distinguished in military as well as in medical circles, died at his home in Washington, D. C., after a short illness, from heart disease, on November 3, aged 77 years. Dr. Sternberg was born on June 8, 1838, in Otsego County, N. Y., received his early education at Hartwick Seminary, and was graduated from the College of Physicians and Surgeons, New York, in 1860. Upon the outbreak of the Civil War he joined the Army Medical Corps as assistant surgeon, and "for faithful and meritorious service" was rapidly advanced. He participated in several engagements during the war and later in the Indian campaigns, was for some time in charge of the United States General Hospitals at Portsmouth, R. I., and at Cleveland, Ohio, was detailed to New York during the yellow fever epidemic of 1871, and was made a lieutenant colonel "for gallant service in performance of his professional duty under fire in action against the Indians at Clearwater, Idaho, July 12, 1877." In 1893 he became surgeon general of the United States Army, and during the Spanish War was in entire control of the medical corps. In 1900 he organized the Yellow Fever Commission, of which Major Reed was chairman. The Army Medical School also was founded during his term of service, which ended in 1902. In 1905 he was made professor of preventive medicine in the George Washington University Medical School.

Dr. Sternberg was a member of many medical societies, among them the American Medical Association, the Association of Military Surgeons of the United States, of which he was president in 1899, the Physiological Society, the Association of American Physicians, the Washington Biological Society (president in 1896), the Washington Philosophical Society (president in 1897), and the Medical Society of the District of Columbia. In recognition of his services he received the degree of LL.D. from the University of Michigan in 1894, and the same degree from Brown University in 1897.

DR. JOHN HENRY HUDDLESTON.

In Memoriam.*

By S. ADOLPHUS KNOPF, M.D.,

NEW YORK.

On Saturday, October 30, 1915, Dr. John Henry Huddleston passed away suddenly after a relatively short illness, his disease having been a double pneumonia. Those near him thought he was gradually improving when suddenly, in the early dawn of Saturday, his great soul passed out. It was, indeed, a shock to the many friends, colleagues, coworkers, and patients when they heard that John Huddleston was no more. Those who had been associated with him in hospital work had seen him only recently presiding over a board meeting with his usual dignity and tact, quiet yet strong. He appeared then in excellent physical vigor.

The funeral was held at the Lenox Avenue Unitarian Church, Dr. Merle St. Croix Wright conducting the ceremony. It was a simple, quiet and impressive service. The church was filled to its very doors with mourning friends, patients, and colleagues; all felt keenly the loss of the man whose personality had meant so much to them. Though only 51 years of age, he had secured many honors, and his life had been one of earnest work and noble achievements.

John Henry Huddleston, born on July 11, 1864, at Boston, Mass., was the son of Charles H. Huddleston and Susan Huddleston. He received his preliminary education in the Boston Latin School and later entering Harvard became a member of the class of 1886, of which he was class secretary. For the twenty-fifth reunion of the class he edited the "Report" and it was characteristic of the willingness with which he undertook the hard work that such a task necessarily imposes upon the compiler for him to write: "If you receive this Report with nearly the amount of enjoyment I have taken in gathering its contents and seeing the faces of one after another of you rise before me, I shall be abundantly repaid."

After taking the degrees of A.M. and M.D. in 1891 at Harvard, he became interne in the Children's and McLean Hospitals of Boston. In 1892 Dr. Huddleston came to New York and established himself as a general practitioner. Among his first and warmest friends in New York City was that good and great man, the Rev. Robert Collyer of the Unitarian Church of the Messiah, who often spoke to me of his affection for John Huddleston. It was not surprising that he soon became remarkably successful in practice. His thorough medical knowledge, his winning personality, and his modest and retiring manner caused him to be beloved by his patients and colleagues alike. The editor of the Medical Record said of him: "Dr. Huddleston was blessed with qualities which made him liked by all with whom he came in relation, and beloved by those admitted to his friendship. In medical practice he was the type of the perfect family physician. Of commanding physical presence, of firm will, but of most kindly and cheerful disposition, his mere entrance into the sick room inspired confidence and hope, and this went far to supplement his medical skill where cure was possible, and in bringing tranquillity and comfort to those beyond human aid." His industry and devotion to the medical profession were soon recognized by his colleagues of the Academy of Medicine who made him its secretary by a unanimous vote in December, 1900, and after faithfully serving as such for thirteen years, he became one of the trustees of this important institution. Because of his high standing in the American profession he was chosen secretary of the International Medical Congress of Madrid in 1903.

In spite of his busy life as a general practitioner Dr. Huddleston also devoted his energy and high intelligence to sociological, civic, and philanthropic works. Thus, when, some fourteen years ago, it was my rare privilege to ask him to interest himself in antituberculosis work he accepted my suggestion with enthusiasm and at once added his signature to a call for the formation of a tuberculosis committee under the auspices of the New York Charity Organization Society. Up to the time of his death he had been one of the most faithful, intelligent, and hardest workers on this committee. His knowledge and sound judgment in matters appertaining to the tuberculosis problem were soon recognized and he was asked to become a member of the Tuberculosis Committee of the State Charities Aid Association, and to interest himself in the formation of the Tuberculosis Clinics Association, of which he became vice-president. He became a member of the National Association for the Study and Prevention of Tuberculosis, an examining physician for the Stony Wold Sanatorium, and an attending physician to the Riverside Hospital-Sanatorium for the Consumptive Poor. Learning of the inestimable services which Dr. Huddleston had rendered to the antituberculosis cause, Governor Hughes appointed him a trustee of the New York State Hospital for Incipient Tuberculosis at Ray Brook, and Commissioner Goldwater invited him to become a member of the advisory board of the City Health Department.

*Read at the Meeting of the Second Annual North Atlantic and the New York State Conferences on Tuberculosis at Albany, Nov. 4, 1915.

Besides this special work in tuberculosis he filled the position of consulting physician to the United Hospital, Port Chester, N. Y., the Messiah Home for Children, and visiting physician to Gouverneur and Willard Parker Hospitals, and the medical board of the latter, in conjunction with the board of the Riverside Hospital, recently made him its president. The first sanatorium for consumptive employees in this country, that of the Metropolitan Life Insurance Company at Mount MacGregor, owes its existence very largely to Dr. Huddleston's initiative. It was in 1908, at the occasion of the Tuberculosis Congress Exhibition in New York, that he arranged for a mass meeting of all the officers and employees of the Metropolitan Life Insurance Company. During the course of the various addresses it was suggested that a sanatorium might be built by the company for its own tuberculous employees. The idea was taken up at once by the officers and directors of the company and Dr. Huddleston became their valued adviser. He helped in selecting a suitable site, supervised the construction of the buildings from a medical point of view, and when the institution was completed became its medical counsellor and consultant.

John Huddleston was a member of the American Medical Association, County and State Medical Socities, New York Pathological Society, Society for Internal Medicine, the Hospital Graduate Club, and the American Association of Military Surgeons. He was appointed assistant surgeon of the Seventh Regiment, National Guard, and retired with the grade of captain. For a number of years, from 1897 to 1911, he was a medical teacher, being chief of Prof. Hermann M. Biggs' clinic, and instructor in medicine at the University and Bellevue Medical College, a position in which he was eminently successful and a work which he assured me often, he enjoyed greatly.

In 1911 he wrote to a classmate the following interesting lines, which give an insight into the lovely and many-sided character of the man: "The last five years have meant for me personally an increasing tendency for private work to fall into the more restricted channels of diseases of the chest and abdomen, a regretted but necessary withdrawal from much of my laboratory study, from teaching, and from military duties, and increasing amount of committee business, largely in 'civic' and 'social service' fields. While during most of the year the days seem all too short, vacations have been a little longer, and the delight of the rush of midwinter is certainly equaled by the fun of the time when there is not a thought of medical or social problems. I am not a sportsman, but I have held a rod with luck attending, and sailed or motored a vacation through, and I have yet to do the same thing in successive vacations, or to find one not magnificent in experience and glorious in retrospect. My fortune is good; my family grows; I would cast a ring into the sea—but my misfortune is clear: I still do not see enough of those who are making '86."

One would hardly think that in a life so filled with daily activities Dr. Huddleston could also have found time to contribute to medical literature, yet he made some valuable contributions to scientific and popular medicine, as the following list indicates:

"A Study of 138 Cases of Pott's Paralysis," *American Journal of Medical Sciences*, August, 1894.

"The Sanitary Supervision of Tuberculosis as Practised in New York," published in collaboration with Dr. Hermann M. Biggs, 1895.

"Two Cases of Noma," *Pediatrics*, October 1, 1896.

"A Discussion of the Composition of Cream and a Consideration of the Desirability of Establishing a Standard," MEDICAL RECORD, September 11, 1897.

"The Value of the Schumburg Method of Purification of Water for Military Purposes," *The Medical News*, December 29, 1900.

"The Method of Preparation of Vaccine Virus in the Vaccine Laboratory of the New York City Health Department," *Medical News*, March 30, 1901.

"The Freezing Point of Urine; Its Determination and the Inferences Which May Be Drawn from It," *The Philadelphia Medical Journal*, June 29, 1901.

"Generalized Vaccinia," *Medical News*, Sept. 7, 1901.

The Wesley M. Carpenter Lecture of 1902 (New York Academy of Medicine), entitled "On Relations of Physical Chemistry to Medicine." MSS.

"Tetanus and Vaccine Virus," *Am. Med.*, Dec., 1903.

"Municipal Control of Tuberculosis," *Yale Medical Journal*, March, 1905.

"Am I My Brother's Keeper?" *Journal of the Outdoor Life*, July, 1911.

"Medical Work of the Tuberculosis Clinics," *Clinic Notes*, April, 1915, Vol. II, No. 2.

Because of his splendid diction and pleasing personality, Dr. Huddleston was much sought as a public speaker and presiding officer at public meetings, yet, although he never shirked duty, he did not care much for public speaking. I remember that it took quite a good deal of persuasion on my part to induce him, on the occasion of a Tuberculosis Sunday, to deliver what might be called his first tuberculosis sermon; and what a magnificent and feeling address it was! He had entitled it "Am I My Brother's Keeper?" I will quote only the concluding sentences. Deploring the inefficiency of hospital accommodation for the tuberculous poor of New York City, he said: "Where is the bed for my recently stricken brother whose best hope is in the sanatorium? Where is the bed for my mortally wounded brother, whose care at home means inevitably more cases of tuberculosis in his family? Forty-five per cent. of those now applying for entrance have to be kept waiting. Such waiting lists —the despair of the doctors—the deaths at home—echo the call. How long shall the call be sounded? How many beds would the waste of inefficient administration in nation, State, or city supply? For want of that dollar wasted my brother dies. You who are citizens of no mean city, and who would take your citizenship at its high value as a share in the administation of the affairs of a brotherhood, have a mighty task set before you, and I hale you to it. But be you citizens or non-citizens, rich or poor, old or young, bear in mind that there is no sanctuary in all this great city of ours to which you can withdraw and be safe. Wherever you are, there is your brother still calling 'Help!'"

Dr. Huddleston's gentleness with his patients, his kindness and sympathy for the lowly and unfortunate, and his devotion to his profession were among the qualities which made him the successful and beloved physician he became. He died altogether too soon, still in the prime of life and in the midst of labors not yet accomplished and dreams not yet realized, yet his life was in a sense complete, well rounded and beautiful and worthy of emulation in every respect. After all it is not the number of years of life which count, but the work we accomplish in the years during which we live.

With John Huddleston's death a man passed from this earthly career whose high conception of religion was duty and service to his fellowmen. As of old, well may it be said of him, "Well done, thou good and faithful servant."

OUR LONDON LETTER

(From Our Regular Correspondent.)

CONFERENCE ON EDUCATION OF DEFECTIVES—ROYAL NAVAL VOLUNTEER RESERVE—HOME OFFICE REPORT ON EXPERIMENTS ON LIVING ANIMALS—DEAD TYPHOID BACILLI; EFFECT ON OTHER BACILLI.

LONDON, October 22, 1915.

AT the call of the National Special Schools Union we have had a conference of teachers and local education authorities, to discuss problems connected with the education of mentally and physically defective children. Mr. Cyril Jackson presided over the first session and said that under ordinary circumstances they would be looking for advance in this work through fresh legislation, but, like everything else, it was overshadowed by the vast struggle in which the nation found itself. He feared that in future there would be an increase of defective adults and they need to see what could be done for the wounded soldier, and in doing so experience with physically defective children would not come amiss.

Sir William Byrne read a paper on "Teaching in Institutes for Defectives," insisting that training directed to specific objects was more practically useful than abstract teaching. Then Mr. J. G. Legge urged that instruction in reading and arithmetic ought not to be overlooked.

Major Waldorf Astor, M. P., who presided in the afternoon, said the evidence accumulated that the cow was often responsible for non-pulmonary tuberculosis. Of course, the ideal was a supply of tubercle-free milk, but it would be years before we get dairy herds free from the infection. He believed in Pasteurization and suggested grading milk into (*a*) children's, (*b*) adults', and (*c*) cooking milk. In New York grading had coincided with a reduction of infantile mortality by over 4,000 in a year, but though the price had risen at the same time, the consumption had also increased to the great advantage of farmer, seller, and consumer. Dr. Elmslie read a paper on the treatment of cripples and was followed by Mr. Coffin of Bradford, and Mr. Spurley Hey of Manchester, who described the special school work in their respective localities.

On the second day Major Leonard Darwin read a paper on "Feeblemindedness in Its Racial Aspects." He said Dr. Tredgold had investigated the families of 61 feebleminded women and found 19 married and had 80 children; of those 80, 16 died in infancy, 20 were physically delicate or mentally dull, and 19 actually imbecile or feebleminded. From this, he said, it appeared that every feebleminded woman who became a mother was likely to produce at least one feebleminded child, and it should be noticed that the families of the feeble in mind were apt to be exceptionally large. If they were properly cared for in institutions and not allowed to become mothers there would be fewer feebleminded in future. He quoted as an instance of heredity, the case of Martin Kallikak who married in 1837; both he and the wife were sound in intellect, and their descendants, numbering several hundreds, had all been normal as far as could be ascertained. But this man had an illegitimate child, the mother being feebleminded, and from that child had sprung 222 feebleminded persons; though the conditions of their lives seem to have been the same as those of the legitimate descendants. In the discussion that followed Dr. Shrubsole hoped the conference would not be unduly depressed, for defects might be due to other causes than heredity; quite half the cases in the schools were not likely to be inherited. Major Darwin in reply to this remarked that when talking to eugenists he insisted on the influence of environment, but when talking to those concerned to provide good environment he insisted on the influence of heredity. He advised Dr. Shrubsole to do likewise.

Mr. J. W. Bunn read a paper on "The Practical Side of Special School Work," pleading that the teacher should be associated with the doctor in the selection of children for special schools.

The surgeons of the Naval Volunteer Reserve have received but slight recognition of their work, although not a few of them have given up good positions, appointments, etc., to serve their country. Their grievances have been represented to the authorities only to be ignored or rejected. The Reserve has been in existence above ten years and includes men who for years before the war have given much time to recruiting duties, for courses of instruction in naval hospitals and the service on battleships. At the outbreak of the war they were, of course, selected to occupy posts on hospital ships where important surgical work was expected. But as at the time the navy was in need of more surgeons, a number were taken on for temporary work, mostly young and some just qualified, and, of course, totally untrained in service conditions. Yet they have been allowed seniority over the more highly trained volunteer reserve—men who have devoted their leisure in time of peace to prepare to serve in war. In some cases surgeons to hospitals have thus found themselves junior in the service and precedence to their quondam assistants, house-surgeons or even their dressers! So unjust and irritating an anomaly ought to be altered without delay. It has been mentioned in Parliament and to the admiralty, but so far without any movement toward remedying what is admitted to be an injustice due to the ranking of the Naval Reserve and Royal Navy above the Volunteer Reserve. So those who in peace time equipped themselves for service in war are beginning to say they might as well have enjoyed themselves until the outbreak, when better conditions would have been offered, or even pressed upon them. The remedy is easy—merely to give the rank of acting staff surgeon to men who have held for several years honorary hospital appointments.

The Home Office Report on Experiments Performed on Living Animals in 1914 has not been completed, but a summary is issued showing the names of the places and persons registered for carrying out these investigations. The number of persons licensed was 678; of these 188 made no experiments in the year and of 8 others no report could be obtained, owing to absence of the licensees on war service. The total number of experiments was 87,253, being 905 less than in 1913. But those in which anesthesia was required numbered only 4,889. The other 82,364 (without anesthesia) were devoted to inoculations, hypodermic injections and such like. During the year 1914, there were 22,371 experiments performed by 19 licensees in investigating cancer, of which more than 21,000 were nearly all on inoculations of mice. For government and public health authorities 21 licensees report above 15,000 experiments concerned with antitoxics, vaccines, and sera, and for testing and standardizing drugs. During the year inspectors have

visited registered places, mostly without notice, and witnessed many experiments. They found the requirements of the act duly observed. Mr. G. D. Thane is the chief inspector and is assisted by a committee of 7 appointed by the Secretary of State for the Home Department.

The power possessed by the blood of persons inoculated with dead typhoid bacilli to agglutinate the *B. typhosus* and some allied bacilli has been the subject of research at the Manchester University under the direction of Dr. Delépine. The study is based on the examination of 280 soldiers injected with antityphoid vaccines in the preceding twelve months. Over 80 per cent. gave a very definite reaction, 16.4 gave no reaction. Between these the percentages were 28.2 very strong, 107 strong, 40 moderate, 8 slight or doubtful. The reaction was more likely to occur on a second inoculation than after a single one—a gradual lessening of reaction was noted with lapse of time; after a month it might disappear rapidly. In only 1 case out of 19 examined within a month was it negative. The relation of agglutination reaction to intensity of post-inoculation symptoms was (*a*) symptoms slight (113 cases), positive 96, negative 17; (*b*) well-marked, positive 138, negative 29.

Against *B. paratyphosus* B. 274 cases were tested, but this bacillus was not very satisfactory, being slightly acted upon by normal sera, but in 9 cases there was slightly stronger reaction. Against *B. enteritidis* 272 cases were tested. Result, 3 sera gave moderate reactions and 4 others slight ones.

1. Non-Tuberculous Cases in the State Sanatoria. Elliott Washburn.
2. Errors in the Diagnosis of Chronic Pulmonary Disease. John B. Hawes.
3. What Constitutes Tuberculosis in Childhood? John Lovett Morse.

1. Non-Tuberculous Cases in the State Sanatoria.—Elliott Washburn asks if we are caring for any cases which, because they are non-tuberculous, ought not to be in the sanatoria. When the Rutland Sanatorium was established nearly seventeen years ago, and somewhat successful efforts were made through examinations by special, skilled examiners to restrict admissions to very early and favorable cases, it was not uncommon to hear the remark even from physicians, "So and so was cured of consumption at Rutland. I wonder if he really had it?" It would seem that the chance of error in diagnosis in well-advanced or far-advanced pulmonary tuberculosis either in adults or children ought to be small. Probably it is, and yet, on the other hand, Dr. Ash, pathologist of the Boston Consumptives' Hospital at Mattapan, reported that although that institution is intended for the care of the tuberculous only, and that most cases are far advanced, in 198 autopsies at that hospital 23 cases or 11.5 per cent. of all cases that came to autopsy proved to be non-tuberculous. In these 23 cases it was found that instead of tuberculosis, the true conditions were pneumonic sequelae in 8 instances, chronic cardio-renal in 5, septicemia in 2, aneurysm of the aorta in 2, malignant disease of the lung in 5, and actinomycosis in 1. He stated that 353 autopsies reported from eight institutions in Massachusetts and other states caring for a similar type of cases of tuberculosis showed 38, or 10.8 per cent., non-tuberculous. If this percentage of variation or error in diagnosis can be accepted as fairly true and constant in patients admitted to special hospitals as advanced in tuberculosis, may we not well ask "What is the percentage of variation in cases which are admitted as early or incipient cases—in which the true diagnosis is admittedly more difficult than in the advanced types?"

2. Errors in the Diagnosis of Chronic Pulmonary Disease.—John B. Hawes states that they occasionally meet with patients who have marked signs of pulmonary disease very suggestive of tuberculosis which later on, usually to their surprise and often to their chagrin, turn out to be due to something else. It is quite unfair to these patients to stamp them at once as advanced consumptives. It is unfair to their sanatoria and hospitals to admit such patients as these while their waiting lists are crowded with real consumptives in urgent need of treatment for themselves and of isolation from others. This paper is based on a series of such patients who had been sent to the writer as probable cases of pulmonary tuberculosis. In each of them he has been forced to the conclusion that the disease was not due to tuberculosis, but to some other cause. The study of these cases has impressed him with the need of taking nothing for granted and not jumping at conclusions, and has emphasized the necessity of a careful and painstaking history, and a thorough routine examination of the lungs and of the whole body, not only once but often repeated.

3. What Constitutes Tuberculosis in Childhood?—John Lovett Morse says that it seems to him that in the first place it is absolutely necessary to distinguish between tuberculous infection and tuberculous disease. Infection may be defined in this connection as the state of being infected, and disease as an alteration in the state of the body or of some of its organs, interrupting or disturbing the performance of the vital functions and causing symptoms of some sort. For all practical purposes, the infant comes into the world free from tuberculosis. In round numbers, 10 per cent. of all infants have become infected with tuberculosis by the end of the first year of life, and at sixteen years not more than 10 per cent. have escaped infection. A very small proportion of these children, however, have tuberculous disease. Tuberculous infection in childhood is almost invariably glandular. The condition is not one of disease unless other tissues are involved or the glandular enlargement is associated with symptoms of disease, such as fever, malaise, debility, loss of weight, and so on. If a positive d'Espine sign is not associated with a positive von Pirquet reaction, the enlargement of the glands is certainly not tuberculous. If a positive d'Espine sign is associated with a positive von Pirquet reaction, and there are signs of acute disease in the lungs, there is no way of determining at once whether the enlargement of the glands is tuberculous or not. If there are evidences of tuberculosis elsewhere, the d'Espine sign is of no importance anyway. If a child has positive d'Espine sign, a positive von Pirquet reaction, shows symptoms suggestive of tuberculous disease, and no foci of tuberculosis are found elsewhere, it is probable that the enlargement of the glands is tuberculous, and that they are not only infected, but also diseased, and the cause of the symptoms.

2. Pituitary Extract.—Dr. Samuel Wyllis Bandler sounds a note of warning regarding the use of pituitary extract, but believes that nothing has been introduced into obstetrics which approaches it in value if it is used in the proper manner and in proper doses. This agent increases the contractile power of the uterus; it is evanescent in its effect, the influence lasting in proper doses about half an hour. He has seldom used more than a third of an ampoule at the first hypodermic injection; occasionally, when necessity demands, he has given one-half an ampoule. This is one of the important factors to be borne in mind; otherwise, it causes an extremely powerful contraction of the uterus which may do harm provided that all the conditions are normal, but which is certainly dangerous if the conditions are abnormal. In a slow, painful, non-progressive first stage of labor, if the head is moulded and fixed it and through the brim, pituitary extract is a splendid help.

4. Hypopituitarism.—L. Napoleon Boston reports two cases of this condition which are illustrative of Fröhlich's syndrome; both cases gave evidence of luetic taint as shown by the Wassermann reaction. At no points over the body did the patients display any hard or painful nodules of fat.

6. The Effect of Smoking on the Circulation.—John Aikman asks if there could be any relation between the percentage increase of tobacco produced and the increase in circulatory disease. A large proportion of our population is exposed to tobacco smoke from early childhood, even if they never became smokers themselves. Much of the air we breathe in homes and public buildings is charged with smoke. Opinions that have been expressed are widely conflicting and we are far from definite conclusions as to the true effects of tobacco.

8. The Treatment of Horse Asthma by Repeated Injections of Normal Horse Serum.—Louis A. Levison says that individuals exposed to the emanations from horses may react in a very characteristic manner, if they are susceptible. Contact with horse by riding or driving, working in the field, entering a stable, or even passing them on the street, may bring on a seizure characterized by difficulty in breathing, sometimes sneezing, a pressure or weight on the chest, or choking spells. The attack may be long or short-lived and may vary in severity, even from the same exposure. Some patients are aware of their susceptibility from their own observations. An attempt to immunize patients by means of repeated injections of horse serum seems entirely rational and was begun about one year ago. Three cases are cited, but the writer does not draw any conclusions from these few cases; they are merely presented to encourage others to try the method in refractory horse asthma.

10. Infant Drug Addicts.—Perry M. Lichtenstein states that textbooks teach that the opiates are excreted through mothers' milk and that the infant born of addicted parents is an unfortunate victim. The effect upon the child *in utero*, when both parents are addicts, is obvious: miscarriage; the birth of a dead child, or the birth of a child showing narcotic poisoning and with an inherited tendency toward taking narcotics. He reports cases which should serve as a warning to mothers and female addicts. The occurrence of such cases emphasizes the fact that the public must be taught the evil effects of drug addiction, and that it is the duty of every physician to warn addicts coming under his care of the serious effects that addiction may have upon their own future and upon that of future generations.

11. An Unusual Complication of Acute Appendicitis.—McW. B. E. Sutton reports this case. On operation they found at the distal end of the appendix a ruptured abscess, firmly adherent to the posterior wall of the bladder, and a beginning peritonitis. The symptom complained of, a sharp shooting pain in the vulva, he believes to be diagnostic of an adhesion to the posterior wall of the bladder.

2. The Essential Factors in the Diagnosis of Chronic Gastric and Duodenal Ulcers.—George B. Eusterman presents this review in order to emphasize proved clinical factors and briefly to consider various phases of experimental, clinical, and therapeutic advancement in their application to the diagnosis of benign, chronic gastric, and duodenal ulcers. The observations are based on the study of 2400 cases of gastric and duodenal ulcers operatively demonstrated in the Mayo clinic from 1900 to 1914 inclusive, with an especial summary of the cases of 1913 and 1914. The average ratio of gastric to duodenal ulcers was about 1 to 3, that is, 75 per cent. of the ulcers were duodenal. Of the 264 cases of gastric ulcer, 171 occurred in males and 98 in females. The average ages were 47 and 44.5 years respectively. The average duration of symptoms was 9.8 years. In about 80 per cent. the course was intermittent. In 50 per cent. the complaint was continuous and the progressive over periods of from several months to several years prior to operation. Irrespective of the location of the ulcer, pain appeared within 4 hours after the ingestion of food in 85 per cent. of the cases; in over 30 per cent. it was present within 2 hours, in 55 per cent. within 3 hours, regarded as constant in 3.8 per cent. and irregular in 3.4 per cent. Definite nocturnal pain occurred only in 6 cases, or 2 per cent. Pain was controlled by food or alkalies, or both, in 180 cases. The majority of these (84 per cent.) showed relief after food, while alkalies alone gave relief in 15.6 per cent. There was a fairly definite history of bleeding in 73 cases, or 27.6 per cent. of this group; about 41 per cent. had hematemesis only, 15 per cent. melena, while both were mentioned in 44 per cent. Gastric analyses were carried out in 255 cases; 38 per cent. of these showed the presence of altered

blood in the extract. Gross retention was evident in 33.3 per cent. The average total acidity was 54; the average hydrochloric acid was 42. In 18 per cent. the acid values were normal or below. Under such a circumstance the possibility of carcinoma, syphilis, or associated disease was evident. The generally accepted complex of ulcer was more or less definitely present in 81 per cent. of the 212 cases; irregular or suggestive in 6.8 per cent.; classified as irregular in 5.3 per cent. In the remaining 7 per cent. the picture was atypical or the record was incomplete. A primary diagnosis of gastric ulcer was made in 174, or 66 per cent.; an alternative one in 21 cases (8 per cent.). Duodenal ulcer was the primary diagnosis in 47 cases (27 per cent.). The Roentgen ray gave definite assistance in 65 per cent. of the 113 cases examined in this series. The situation of the ulcers was as follows: The lesser curvature in 167 cases, or 63 per cent.; the pylorus, 35, or 13 per cent.; total ulcers at or near the pylorus, 87, or 33 per cent.; posterior wall 6, or 2 per cent.; 2 gastrojejunal ulcers secondary to gastroenterostomy. Multiple ulcers were noted in 15 cases, or 5.6 per cent. The complications were: Advanced cicatricial pyloric stenosis, 11.7 per cent.; evidence of perforation, 28 per per cent.; perigastritis with adhesions to neighboring structures, 28 per cent.; questionable malignancy, 11.7 per cent.; appendical disease, 33.7 per cent. In less than 25 per cent. of all cases was there no complicating factor. Of 814 cases of duodenal ulcers 628 (77 per cent.) were males and 186 (22.8 per cent.) were females. The average age was 43 years, and the average duration of symptoms was over 12 years. The clinical course was intermittent in 95 per cent. of all cases, and periodic in 50 per cent. Continuous preoperative complaint of variable duration was noted in 26 per cent. Definite relief by food was noted in 67 and partial or irregular relief in an additional 15 per cent. Relief by neutralization was present in 39 per cent. Hemorrhage was reported in 208 cases (25 per cent.) and was classified: Melena, 8.8 per cent.; hematemesis, 6 per cent.; both 10.5 per cent. A primary clinical diagnosis was made in 543 cases (66.7 per cent.) and an alternative one in 67 cases. Of 251 cases in which the tentative diagnosis of gall-bladder disease was also made, 51 (20 per cent.) showed this disease present and 51 ulcers (22.3 per cent.) were shown to be of the chronic perforating variety. The ulcer complex was fairly regular in 71 per cent., suggestive in 7.2 per cent., and irregular in 13.2 per cent.

3. Medical Aspects of Open-Air Schools.—Sherman C. Kingsley considers the problems of child life and the practicability and advantages of open-air schools. He states that open-air school advocates believe that 100 per cent. of the school children should have their fresh air and hygienic rights. In many parts of the country there is no reason why all schools should not be open-air schools all the year around, because the climate affords no serious obstacle. The open-air school movement is spreading rapidly over the country. There is a deep interest in the physical welfare of school children, and it is the conviction of part of our people that the time to serve these children is when they are in the public schools; that it is not good business to allow them to sit for six or eight years with handicaps and defects which are preventing them from receiving the thing which the school wants to give. He calls attention to the fact that there are 20,000,000 school children in the United States. These boys and girls spend 11,415 years in the school rooms of the land every school day. This means a total every school year of 2,283,000 years. He calls attention to the amount of time that is lost through drowsiness, inattention, and half asphyxiation, due to badly ventilated and overheated school rooms. The work of conducting open-air schools should have careful medical direction and supervision.

4. The Sanitary Engineer in Public Health Work.—Samuel Dixon and B. Franklin Royer believe that for efficiency a public health organization in a representative form of government should be directed by one versed in sanitary and practical medicine, as well as in sanitary engineering. A little training in entomology and geology would add to the efficiency of the executive. Coordination is the keynote of a successfully organized public health department and the sanitary engineering division is one strong arm in such an organization.

6. A Method of Testing Muscular Strength in Infantile Paralysis.—E. G. Martin and Robert W. Lovett state that the determination of the strength of partly paralyzed muscles in infantile paralysis has been done in the past by the roughest sort of guess, most often by pressing the hand against the contracting muscle. It was suggested by the physiological department of Harvard University that a more accurate means of estimating muscular strength would be of great value, and the method described was formulated with the following aims: (1) to enable a more accurate diagnosis to be made in the way of picking out the seriously affected muscles after an attack; (2) to obtain a means of indicating the muscles which were most promising for mechanical or operative treatment; (3) a quantitative measurement of this sort which would give a means of gauging the effectiveness of different modes of treatment; (4) a method of this kind might enable one to pick out from supposedly abortive cases certain cases in which remained a residual muscular paralysis too slight to be perceived by other methods. The index of muscular power employed is the resistance of the muscle group to a steady pull sufficient to overcome it. A sling is adjusted in an assigned position over the part of the limb in which the muscle group to be tested has its insertion. The sling is fastened to an accurate spring balance through which the pull is exerted. The balance must be held carefully in a line at right angle to the axis of the part of the limb to which the sling is adjusted, and is read either at the instant the muscle yields, as in the test of plantar flexion, or when the member is drawn into an assigned relationship with the body, as in knee extension. A standard technique has been worked out for certain movements.

8. Postoperative Detachment of the Choroid, with Especial Reference to Elliot's Operation for Glaucoma.—Hans Barkan concludes that clinically demonstrable postoperative detachment of the choroid takes place after cataract operations, with or without iridectomy, in about 4 per cent. of the cases; in Elliot's trephine operation in about 10 per cent.; in Lagrange's sclerotomy in about 20 per cent.; it does not occur in linear extraction, or simple iridectomy. The *sine qua non* for its existence is low intraocular tension, caused by abnormally rapid escape of aqueous humor through the wound, extending over some interval. The chamber is not shallow or absent because of the detachment; the detachment is secondary to the condition of the chamber. The fluid responsible for the detachment is derived, probably, from the choroidal blood vessels, and not improbably from the veins. Choroidal detachment is of relatively frequent occurrence after Elliot's trephine operation and should, if for statistical purposes only, be looked for, and its occurrence noted in all cases in which Elliot's operation has been performed.

10. Clinical and Electrocardiographic Studies on the Action of Digitalis.—Alfred E. Cohn states that their

studies have led them to draw a number of conclusions in regard to the way digitalis acts, and to find new criteria in the T wave and in the effect on conduction for detecting when the drug is acting. It seems important to emphasize the fact that it is essential to distinguish differences which patients suffering from heart disease present, and to study them in groups, with these differences in mind. Rhythm certainly offers a prime basis. The effect of digitalis on rate and on a number of other capacities varies with the nature of the disturbed function. In the use of the drug in pneumonia we have found it to have an action essentially similar to that found in the nonfebrile diseases. In the absence of edema, we have not observed a diuretic effect. Evidence has been found which indicates persistence of action, longer than can be accounted for if the drug acts only by virtue of its concentration. The writer believes that clearness of indications will result only if the exact mechanism of the action of the drug is ascertained.

13. Malignant Tumors in and Around the Orbit, with Report of Starvation Method of Treatment.—E. H. Cary reports twenty-four such cases and concludes as follows: 1. (*a*) All branches of each external carotid must be tied. (*b*) In the majority of cases both sides can be operated on without an interval of two weeks, and this without shock. (*c*) Sarcoma offers the best results. 2. It may be noted that all the sarcomas occurred on the left side, except two. As the common carotid arises from the transverse portion of the aorta, a morbific tendency might find nourishment in excess from this circumstance. 3. Circulation from the ophthalmic branch of the internal carotid does not prevent the value of the operation in the orbit, as Dawbarn concluded. 4. In this group of cases, sarcoma occurs in all ages. In females it occurs most often beyond the age of 19, and in males, under this age. 5. Cancer occurs in this group oftener in males and only in one case under 46 years of age, which was the ethmoidal case of 28, coming under Case 6 (sarcoma). 6. I have not found in any of my cases an anomaly in the carotid distribution. 7. The results seem best when the tumor is not disturbed, suggesting traumatism at the sight, always an exciting factor. 8. Though I have not practised ligating uniformly the accompanying veins, it may be better to do so. 9. Although certain carcinoma cases were treated with the Roentgen ray, no good results were observed. 10. In two cases in which tumors involved the optic nerves—Case 9 secondarily and Case 10 primarily—both demonstrate that the optic tracts reach the chiasm and there decussate; when a nerve proceeds to its destination, the respective nasal half possibly, and the temporal half probably are separately sheathed, as is also the papillomacular bundle of fibers, which are intact and which may be disturbed but not destroyed.

1. An Address on the Ethics and Law of Drug and Alcohol Addiction.—William Collins delivered this lecture before the Society for the Study of Inebriety on October 12, 1915. He discusses the subject from the standpoint of free will and personal liberty and says that alcohol and drug addiction are to be regarded as examples of the surrender of self-control in favor of self-indulgence, of the voluntary preference for the lower in the presence of the higher alternative of volition, exercised in obedience to appetite rather than to the higher command of conscience. If we call inebriety a disease we must not thereby acquit its subject of all responsibility; if we call it a vice or a crime we must not on that acount relinquish remedial in favor of purely punitive treatment. He points out the need of radical reform of the pharmacy and poison laws, takes the position that alcohol is a drug and a poison, and that its use should be restricted, not by prohibition, but by restriction of preparations containing more than a moderate percentage of ethylic alcohol as if they were, what in fact they are, poisonous drugs. He also points out that legislation too far in advance of public opinion is difficult of enforcement and is liable to reversal by reaction or to fall into disrespect by aiming at more than can be achieved.

2. Clinical Characteristics of Cases Treated as Paratyphoid Fever.—Henry Robinson, while serving the British Expeditionary Force, has had the care of a number of cases whose clinical characteristics differed from anything he had met in civilian practice. The series observed consisted of 89 patients admitted to the enteric isolation wards. All cases of typhoid fever were excluded, and also several of a very mild type which were clinically paratyphoid cases in which the *Bacillus typhosus* was isolated. Of the eighty-nine patients, in forty-seven a paratyphoid bacillus was isolated from the blood, feces, and urine. Of the remaining forty-two cases a small number were perhaps not enteric cases at all, but the clinical course of the great majority of them resembled so strongly that of the former group that probably more complete investigation would have resulted in isolation of a paratyphoid organism. The writer found that paratyphoid fever (A and B) in the British Expeditionary Force is a disease much shorter and milder than typhoid fever, as met with in civilian practice and in the South African campaign. Its onset may be gradual or moderately sudden. Headache and abdominal pain are its most constant symptoms. Shivering at the onset; cough, pains in the limbs and back, diarrhea, constipation, and nose-bleeding are the next commonest symptoms; all these are met with in about 30 to 60 per cent. of the cases. Vomiting at the onset and sore-throat later are by no means rare. Definite rose spots in successive crops are found in about 60 per cent. of the cases. The abdominal reflex is absent in slightly less than 50 per cent. of the cases. The pulse rate is extraordinarily slow, even more so than in typhoid fever. Relapses of brief duration are not uncommon. Several complications occur more rarely and are the counterparts of those associated with typhoid fever. The paratyphoid bacillus, A or B, is frequently isolable from the feces, but in many cases not until the symptoms have subsided; it is also occasionally isolable from the blood, urine, and from metastatic abscesses. Distinct help is obtainable from repeated quantitive Widal reactions, but much experience is required for their interpretation and they must be read in conjunction with clinical evidence and the history of previous inoculation. On the assumption that this disease is of the enteric group the same precautions against its spread are indicated as in the case of true typhoid fever. In particular, carriers must be watched for.

4. **Cerebrospinal Fever.**—Halliday Sutherland says that we have long known that epidemics of cerebrospinal meningitis arise under cold atmospheric conditions and disappear with the advent of warm weather. In general cold air is lethal to the organism of this disease and it is impossible for infection to be carried by cold air. Overcrowding, bad sanitation, and privation are well known as predisposing causes. In the relationship between these circumstances will be found the keynote to the etiology of the disease and to a simple method of preventing it. Man by protecting himself against cold in an unphysiological manner has produced the ideal conditions for the growth and spread of this malady. The prevention of the disease is simple. In dormitories or day-rooms where men are congregated the windows should be open day and night. The greater the overcrowding the more thorough should be the natural means of ventilation. With an unlimited supply of fresh air cold is to be guarded against by suitable clothing, the avoidance of draughts, and of damp garments that draw heat from the body.

5. **Transient Aphasia, etc., Due to Arterial Spasm.**—J. Gordon Sharp reports a number of cases illustrating types of aphasia, monoplegia, hemiplegia, or hemiparesis, which were for a long time not clearly recognized. He states that they are neither embolic, hemorrhagic, nor thrombotic in origin, but depend on a temporary spasm of the middle cerebral artery or its branches. The condition is usually met with in those who have passed middle life and in those who are subjects of arteriosclerosis. Arteriosclerosis does not alone account for the spasm, and it is likewise not always associated with high systolic blood pressure. Passion and emotion may be exciting causes, and so may toxins circulating in the blood. The cerebral arteries are not more frequently atacked than others but the results are more evident. Some have said that in the transient hemiplegia under consideration extensor plantar reflex does not occur. This is not the experience of the writer, who has often demonstrated its presence. The author discusses the treatment, preventive and immediate. Alcohol, tobacco, excitement, and vitiated atmosphere are certainly determining causes in those liable, and should, therefore, be avoided. The treatment is practically that for arteriosclerosis and high systolic blood pressure.

6. **Labor Complicated by Eclampsia and Glycosuria.**—C. Percival White reports this case in which sugar was demonstrated in the urine as early as the fourth month of pregnancy. During the pregnancy the peculiar features of the urine were the small amount of albumin, the presence of a considerable but varying amount of sugar, and the possibility of producing almost at will, by diet, increase and decrease alternately of each. Between the thirty-fifth and thirty-sixth weeks cesarean section was carried out in consequence of puerperal eclampsia and the impossibility of delivery through a long conical cervix. The result of this case seems to modify somewhat the general idea that surgical interference in diabetics is rarely successful and often fatal; it moreover invalidates the statement that owing to the almost universal death of the fetus in pregnancy diabetes the mother's life alone should be considered. In this instance the development and birth of a healthy child was quite contrary to experience. Another dictum usually accepted is that should the mother survive labor or abortion, the prognosis is never favorable. This did not hold good in this case, since this patient has improved and at the end of three years has gained seven pounds in weight. This is probably largely due to unremitting care and attention.

7. **The X-Ray Treatment of Fungating Epithelioma.**—Christopher Kempster states that during the past few years he has been able to treat a large number of malignant growths and to observe the effect of various methods of filtration upon this particular form of growth. He finds that those cases which gave the best results in his hands were the ones treated by what is termed the "progressive filtration" method—that is, the gradual introduction of filters of progressive thickness. It is his custom to deliver to cauliflower fungations a full pastille dose of the rays without any filter whatever at a distance of 10.6 cm. from the anticathode, since the soft short rays from the *x*-ray tube have a singularly rapid atrophic effect when delivered in full pastille doses. This dose is repeated two or three times at weekly intervals. At the end of this time the growths have usually shrunk in a remarkable manner. An aluminum filter 1 mm. in thickness is then introduced at two or three sessions, at weekly intervals, and then successively thicker filters are used. In this way a number of satisfactory results have been obtained. The writer cites illustrative cases.

8. **The Irrigation of Wounds.**—Almroth E. Wright states that the irrigation of wounds has the following advantages over the application of wet dressings: 1. A therapeutic solution can be continuously applied, maintaining its concentration unaltered, and this, in treatment with saline solutions, is of fundamental importance. 2. With proper arrangement the therapeutic agent can be applied to all internal and external surfaces of the wound and at the same time efficient drainage can be obtained. He describes an arrangement of bandages by means of which the water can be led into the wound where it is required, can be distributed so as to wash down all the walls, and can then be carried away without any leakage into the bed. The principle of the siphon is employed with either a single or a multiple loop method of packing. The writer for this purpose classifies wounds into cylindrical wounds disposed horizontally, funnel-shaped wounds with the funnel opening disposed upward, downward, and laterally, and, finally, ascending or descending cul-de-sac wounds, and shows how in each particular type of wound an arrangement can be made for feeding in the therapeutic solution, for distributing it over the walls, and then effectively draining the wound.

5. Memorandum on the Employment of Bandages for the Irrigation of Wound-Surfaces with Therapeutic Solutions, and the Draining of Wounds. Almroth E. Wright.

1. **Ureteral Calculus.**—David Newman states that many other lesions of the urinary tract may present all the symptoms of calculus, so that when the surgeon had only subjective symptoms as his guide, helped only by palpation and examination of the urine, the cases were very rare in which even an approximately correct diagnosis could be made. The problem is now greatly simplified and the diagnosis reduced to a certainty. With the aid of the *x*-ray, the cystoscope, wax-tipped and metallic ureteral bougies, and palpation of the terminal portions of the ureters, exact information can be gained. Even with these valuable aids, in a goodly number of cases, patience, careful watching, and repeated examinations may be required before a definite course of treatment can be determined. Conversant with all the recent advances both in scientific and practical urology, the surgeon realizes the value of the

physical corroborative evidence in helping him to gain a full knowledge of the lesion. In a few instances the employment of all the special methods may be necessary in order to make a diagnosis; in others one may suffice. The author cites instances in which the employment of one method has yielded the diagnosis, but states that such cases are not met with every day and consequently all methods which throw light on the diagnosis are of use. Of all these methods the radiograph is probably the most useful, but should never be allowed to become a short cut to diagnosis because of the many dangers of obtaining shadows which are liable to be taken for stone.

2. **Removal of a Bullet from the Heart.**—L. H. C. Birkbeck reports this case which occurred in a private, who was wounded eight days previous to his admission to a general hospital. The bullet had passed through, and killed a man in front of, him. The patient had not lost consciousness and had experienced only slight pain from the wound. There was a small dirty wound, one-half inch in diameter, just below and to the right of the xiphi-sternal junction, and also a painful swelling of the right parotid gland, which disappeared the following day. The heart appeared to be normal and regular. The *x*-ray examination seemed to show an object in, or close to, the lowest portion of the wall of the right ventricle. Its shape and size so far as could be made out were those of a rifle bullet. Five weeks after the patient had received the wound sharp pain developed in the left leg and the heart showed irregularity and dropped beats; operation was decided upon. Five grains of veronal were given the night before the operation and five-sixth grains of morphine during the morning before the operation. The patient was not unduly under the influence of morphine. Under local anesthesia (eucaine 1 per cent. potassium sulphate ¼ per cent. and adrenalin) Colonel H. M. W. Gray made a horse-shoe incision, with the convexity upward, extending along the sixth costal cartilage on each side and across the sternum at the level of the attachment of the fifth cartilage. This made an exposure of the track of the bullet in the depth. The perichondrium was separated from the left sixth cartilage, which was cut across at the costochondral junction and used as a lever to elevate the sternum, while the triangularis sterni, pericardium, etc., were being separated off the posterior aspect of the flap. A small portion of the sixth rib was removed close to the costo-chondral junction. The sternum, at the lower border of the fifth costal cartilages, was grooved deeply with a gouge and divided with bone forceps. The soft parts were then separated from the sternum and ribs so that the flap could be turned downward and forward. When the flap was pulled forward a hole about an inch long appeared in the pleura on the right side in the track of the bullet. The right lung collapsed, respirations became labored and quick, and the patient coughed jerkily. This was apparently the only discomfort that the patient experienced during the operation. The pericardium was opened obliquely, from the base to near the apex of the heart. The heart looked normal and no wound could be seen. On digital exploration the bullet was felt to be lying apparently fixed at the back of the heart either in the wall or the cavity of the right ventricle. The right ventricle was seized with a pair of catch forceps near the apex and a suture was passed through the muscle adjacent, thus holding the heart forward. Manipulation of the bullet caused it to change position and it was found to be free in the ventricle. It was worked as far as possible from the coronary vessels, grasped between the thumb and finger and two stitches were inserted in the muscle wall over the bullet. The wall of the ventricle was incised for half an inch, and the bullet removed with forceps. While the wall of the ventricle was still held firmly between the thumb and finger the stitches were tied. On removing the catch forceps there was brisk bleeding which was stopped by an under-running stitch. The pericardial cavity was wiped free of blood clot and filled with normal saline solution to exclude air and was then sewn up. The right pleural cavity was next filled with saline and sewn up. While the wound was being closed the chest was aspirated to remove the saline. The patient was wonderfully comfortable on being taken back to bed, but about four hours after the operation the respirations rose suddenly to 48 a minute and remained at that level until he died four and one-half days later. There was never any indication that the operation had interfered with the heart action, which averaged 120 to 130 and was wonderfully strong until within a few hours of his death. From an examination of the heart post-mortem it was found that the wounds in the heart had healed perfectly. The cause of death was judged to be multiple pulmonary infarction from clots derived from the right ventricle.

3. **Drainage of Gunshot Wounds.**—Max Page states that the rubber tubing commonly adopted for drainage has not been entirely satisfactory in war surgery. In its place he substitutes a tube made of rubber, which in section is star or pinion shaped. The outside diameter should be the same as that of ordinary full-sized drainage tubing. For certain cases the drain should be provided with a central lumen. The tube is passed through the entire length of the wound track. As a result of this arrangement a series of gutters lie against the wound surface and extend the length of the tract. When fluid is syringed into the cap it passes down each gutter, so that it is brought into contact with practically the entire wound surface, at the same time clearing away from the same area all débris. Theoretically it might be expected that this drain would give good results with continuous irrigation, but in practice relatively forceful periodical washing out of the gutters has proven more satisfactory.

The Meiostagmin Reaction in Malignant Tumors.—Wissing recalls to the reader that this reaction is bound up in the mensuration of the depression of the surface tension which appears upon the addition of suitable antigens to the sera of cancer patients. This reaction is by no means specific for malignant tumors, for it is seen in other affections which behave themselves in the same manner. Fortunately there is no danger here of confusion and differential diagnosis. It is necessary, however, to know in just what conditions a positive meiostagmin may occur. These are as follows: (1) Febrile states. Here the reaction is transitory and subsides not long after the fever. (2) In nearly all pregnancies in the last 3 or 4 months, disappearing as a rule about two weeks after delivery. (3) Heart disease with broken compensation. (4) Cirrhosis of the liver and icterus gravis. (5) Pulmonary phthisis, afebrile, with large area. (6) Individual cases of marked diabetis mellitus (acidosis plays no rôle here). (7) Individual cases of chronic rheumatic polyarthritis. (8) Individual cases of pronounced chronic nephritis and uremia. Of all these conditions but one need be associated logically with possible cancer formation; this is jaundice, which could be due to cancer of the gall bladder or liver. If due to cho-

lelithiasis this should soon become apparent. There are numerous severe states in which a meiostagmin reaction is absent—these at least cannot cause confusion in diagnosis.

Ethylhydrocuprein in Scarlet Fever and Measles.—Hirschfelder and Schlutz, both of the University of Minnesota, speak of the fine results from the use of this quinine derivative in pneumococcus sepsis, both as prophylactic and curative. Giemsa and Werner, Izar and Nicosia have shown its great superiority over quinine in malaria. Having obtained some of the drug from Professor Morgenroth the authors have been testing it in scarlet fever and measles. In the former no favorable influence on the course of the disease was noted. The fever even lasted a little longer than in control cases. The results in measles were different. Whereas in control cases the duration of the fever averaged practically 8 days, under the use of the drug the duration was almost cut in half (4.3 days). The dose was from 1½ to 3 grains three times daily. The drug was tested in experimental rabies and experimental vaccinia with negative results.

Münchener medizinische Wochenschrift.

September 21, 1915.

A New Quinine Derivative as an Oxytocic.—Herzog describes a new drug which may come to supplement pituitrin and ergot. That quinine posses a certain amount of oxytocic and abortifacient action has long been known, and noted obstetricians have tested it within comparatively few years; and in fact were thus engaged when the hypophysis preparations were placed on the market. Were it not for the uncertainty of its action quinine would be placed by some authorities at the head of the column of oxytocics. Still when used intensively the percentage of positive results has often been high. The discovery was made that a combination of quinine and veronal is much superior to quinine alone in obstetrics. At von Herff's clinic during the past year a combination of the two has been used in 150 cases of childbirth and chiefly during the period of dilatation. The treatment was successful in from 70 to 75 per cent. of cases. The drug acts only when some pains are actually present and cannot create pains. It appears in fact to sensitize the uterus to the natural exciters of the pains. On account of its tendency to act chiefly in the first stage of labor, it can be followed up by hypophysis extract or ergot. In a few cases of beginning abortion the quinine derivative has caused prompt expulsion of the ovum but these cases were the exception.

Prevention of Epidemic Cerebrospinal Meningitis.—Petruschky, who has been forced to deal with an epidemic cumulation of cases in soldiers' barracks, gives an outline of how his successful results were obtained. The methods employed differ in one respect from those recently reported from Zürich. In that city the preventive measures were not specially stringent. Isolation of suspects was practiced, but when these did not develop the disease in two weeks they were released even if carriers. But the Zürich troops are not at war, so that the management can deal with suspects more liberally than during actual war at the front. The author, in carriers and by actual cases of disease, disinfected the room and patients' belongings, and special attention was given to pocket handkerchiefs. Everyone had to be accounted for, and they were not sent to the laundry until disinfected on the spot. The handkerchief order was enforced among the carriers. The idea came from the fact that after earlier measures had been enforced new cases still occurred; since the measures were directed to handkerchief disinfection no new cases have appeared.

Serological Studies in Tetanus Subjects.—Noeggerath and Schottelius have sought to determine whether the serum of patients and convalescents contains definite amounts of natural antitoxin. In such cases either no serum should have been given for prevention or treatment, or, when given, its protective power should if possible be determined on animals. In a large number of cases tested both patients and convalescents showed in their blood antitoxin equal to a 1/10 fold serum. It was found impossible to allow for the protective value of serum already injected. The conclusion from these experiments is that the convalescent serum of a tetanus patient is not powerful enough to be used in treating the disease.

Deutsche medizinische Wochenschrift.

September 23, 1915.

Scrofula.—Schelble states that if we abstract actual tuberculosis from clinical scrofula, the exudative diathesis remains. Tuberculosis is often associated with the latter, but apparently not in the obligate sense. The socalled scrofulous facies appears to represent sufficiently the exudative diathesis, but certain details may have a tuberculous origin. Swollen cervical lymph nodes readily arise in nonspecific lesions of the face, fauces, etc. These should not be excised even if there is suspicion of tubercle, for now we have such resources as the *x*-ray and quartz lamp. Of great importance is the subject of phlyctens on the conjunctiva, which lesion alone can set up much of the so-called scrofulous facies—impetiginous eczema of the face, swollen upper lip, swollen lymph nodes. These phlyctens can sometimes be traced to external infection, but there is also some endogenous factor. Is this tuberculosis? Half or less of those tested with tuberculin give a positive reaction, even if we exclude all cases presenting the clinical appearances or family history of the disease. It is doubtful if two varieties of phlycten exist, and of the two sources the exudative diathesis seems the choice. As an exogenous factor acting upon the latter may be mentioned the head louse which attracts to the scalp numerous pyogenics. The presumably non-tuberculous lesions of scrofula yield to measures which would hardly prevail were these lesions tuberculous or the expression of tuberculosis.

Influence of Morphine on Heterotopic Cardiac Stimulation.—Hering first cites old clinical observations and the results of animal experiment. W. T. Porter, the American physiologist, showed in 1896 that morphine favors the appearance of heterotopic stimulation of the organ. In 1891 Curschmann stated that in angina pectoris he had more than once seen death follow suddenly upon a large hypodermic of morphine. The latter is able to favor heterotopic stimulation both directly and indirectly. Indirectly it acts upon the vagus, increasing its tonus. Directly by acting on the accelerans it favors auricular flutter and this is doubtless how it caused the angina pectoris deaths. This action of morphine is hardly to be found in works on pharmacology, but various clinicians have urged much caution in the use of the drug in heart disease.

Functional Aphonia.—J. F. O'Malley states that six cases of this condition have come under his care, all having occurred in the trenches. In four cases the voice returned on asking the patient to phonate with the laryngeal mirror in situ for the purpose of examination, and a mild application of the faradic current was effective in the other two cases.—*Proceedings of the Royal Society of Medicine.*

Insurance Medicine.

War Mortality.—It is an axiom that losses in war must increase with the frequency of opportunities for losses and with their duration. Hence the number of fighting days in which great pitched battles are fought should be in direct proportion to the total losses of the war. In the Russo-Japanese war there were 40 such days. The losses by disease cannot be calculated because even under poor sanitary conditions the Russian losses of this sort were less than a third those of the Japanese. The latter were due largely to defective nutriment and beriberi.

A battle must be most carefully prearranged at the present day. Often this involves forced marching, and the troops may have to fight before they can rest. It may so transpire that these particular bodies have to face an invisible enemy as a result of which they become demoralized by losses before they can retaliate. There is a natural tendency to spread and seek cover and then regroup themselves, but since there has been no opportunity prepared for such a course they can only yield, for modern fire is quite irresistible.

In every contest moral and psychological factors play a notable role. In former times friends and comrades marched side by side, with flying banners, singing and cheering; while today the soldier fights alone in a trench or under other shelter, and hears whizzing bullets from invisible foes. He can see the fall of his neighbors. It all wears on him until demoralization sets in, which means efforts to save himself.

The losses in battles of position are naturally less than in battles of motion, so that in trench-warfare this should be the case. In the Russo-Japanese war, however, it was an instance of the most tenacious defence against the most fanatical attack. In position-warfare there are but two objectives—either to outmaneuver the enemy or to disperse him by artillery fire. The only other course possible would be for both to come out from their shelter and fight. Hence despite the vast increase in the technique of slaying, losses are much lower than in former generations. We may look forward to still smaller percentages of loss in warfare. Progressive evolution of strategy and tactics, more humane infantry bullets, advances in medical science, are among the factors which will bring this about.

To visualize these statements it is only necessary to note the fact that war premiums in Bulgaria in 1913 varied from 6 per cent. in the young to 3 per cent. in the older troops. Despite the losses of the two wars war insurance was afterward issued by the Balkan Co. without any premium, save a flat rate, single payment of 2 per cent. on taking out the policy.—*Blätter für Vertrauensärzte der Lebensversicherung*, May-August, 1915.

Referees and Examiners.—Mr. Isaac Miller Hamilton, president Federal Life, Chicago, in discussing the papers read before the fifth mid-year meeting of the Medical Section of the American Life Convention at French Lick, Ind., said that personally he believed that the business end of the medical departments of the life insurance companies had increased wonderfully in efficiency during recent years. In reference to the matter of a referee, it was one thing to have a referee who had nothing to do for the company except occasionally to name an examiner and quite another for the company to use the entire time of a capable referee who relieved the medical director of the work of appointing local examiners. Companies of the size of most of those having membership in this bureau would not find it practical perhaps to employ a referee to give his exclusive time to the service of the company. His personal observation and judgment led him to believe that unless companies were in a position to have such a service it was much better to cultivate a feeling of cooperation between medical directors. They should frequently compare their lists and freely exchange information. If a company was entering new territory its medical director should ask two or three or more of the medical directors of other companies if they would furnish him with their lists of medical examiners for the territory and respond promptly when similar requests were made of him.

Dr. Florence suggested that agents should not have blanks for appointing examiners, but that these should be sent from the medical department. With that general statement he was in complete accord; but as with all dogmatic rules, there perhaps should be some exceptions. With this fundamental requirement the agency department of a company should cooperate with the medical department and the cooperation must be begun at the time the agent was appointed. In his judgment, moreover, it should always be made clear to the local examiner that his actual appointment and the continuance of that appointment rested with the medical director, not with the agent; that the company had confidence in its agents and hoped there would be cooperation to the fullest possible extent between the agent and the examiner, but there would be a very full investigation by the medical director when differences of opinion arose.

Disputed Cause of Death.—Action was brought on a policy of insurance providing that, if death resulted from bodily injuries "effected directly and independently of all other causes through external, violent, and accidental means," the insurer would pay the sum of $2,000, and if death resulted from wounds "intentionally inflicted upon the assured by any person," the insurer would pay $400. The assured was intentionally attacked and stabbed. Gangrene of his wounds followed and he soon after died. It appeared from the testimony of the physicians who dressed his wounds and attended him that gangrene is one of the consequences that might follow an open wound, and that the insured died as a result of the gangrene, which was caused in the first instance, by the wounds, and that there would have been no blood poisoning or infection of any kind but for these wounds. It was also shown by the evidence that this infection may be produced as the result of the failure of the surgeon, who dresses the wounds, to properly disinfect his instruments; or, in other words, that gangrene or blood poisoning may set up in a wound as the result of very slight neglect or inattention, or from any cause that brings into contact with the wound some unclean object. The son and wife of the insured testified, in substance, that two days before he died they cut or untied the bandage around a wound on his thigh with their hands, and that he rubbed his hand over the wound. The court thought that it would be pure speculation to say that the cause of the death of the insured was gangrene produced by the removing of the bandages and the rubbing of the wound. The insurer was, therefore, held liable only in the amount of $400.—Casualty Co. of America v. Taylor, Ky. Court of Appeals, 176 S. W. 194.

Society Reports.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

Forty-first Annual Meeting, Held at Lexington, Kentucky, October 19, 20 and 21, 1915.

(Special Report to the MEDICAL RECORD)

THE PRESIDENT, DR. HUGH CABOT OF BOSTON, IN THE CHAIR.

The Principles of Cleft Palate Surgery. — Dr. JOSEPH RILUS EASTMAN of Indianapolis said failure in palate operations could often be traced to indifference or uncertainty on the part of the operator as to how provision could be made for arterial communications into the flaps. Naturally in deciding any case the question of whether lateral incisions were necessary the principle that there must be no tension upon sutures could not be slighted. No sutured cleft palate would heal if the coaptation sutures were under tension. However, lateral incisions were not under tension. the matter of preventing tension. If the flaps were freely and completely elevated from the hard palate, the soft palate split along the edge of the cleft and the tensor palati aponeurosis divided, there was usually no trouble in bringing the lateral halves of the palate together without tension and when they were thus drawn together they were red and vascular and in the most favorable condition for union. In turnover flap operations one severed practically all of the arteries which entered the flap excepting the very small branches which entered along the margin of the cleft where the flap was turned over. Such poorly nourished flaps did not always die nor did they always live. Certainly their viability varied with their blood supply, other things being equal. A surgeon was unfair to his patient and himself if he failed to minimize hemorrhage in every possible way during cleft palate operations. Avoidance of injury to the palatal vessels and the consequent hemostasis were of obvious value in keeping the field clear for accurate work. This was not a slight advantage. Often in a small mouth and irritable pharynx the presence of blood sufficed to make a "dismal swamp" operation of what otherwise would be a comparatively simple affair. But as essential as the blood-free field was to precise work there was a much more important aspect of the hemorrhage question. The hemorrhage not rarely led to a fatal result, perhaps through shock, perhaps through swallowing of blood with its fever inducing constituents, perhaps through the general effect of lowered vitality. For many reasons that operation was best which could be performed with the least injury to blood vessels. In wide palatal clefts the prospect of success without lateral incisions might not seem good. One might readily receive the impression that there was little or no palatal tissue to be freed and elevated by scissors-spreading dissection beginning at the edge of the cleft, the temptation to make lateral incisions in such a case being great. However, it might be said that soft palatal tissue was more abundant on the sides even though widely separated by the cleft than would be imagined by those who did not make it a practice to relax, unfold, and develop the lateral halves of the cleft palate by blunt dissection, beginning at the cleft margins. The palatal tissue was there. It was our duty to free it, smooth it, and thus broaden it. It certainly was not in the line of our duty to ruin its viability by severing its vessels in making lateral incisions.

Dr. TRUMAN W. BROPHY of Chicago said the subject of cleft palate and hare-lip had been less considered than any other in the domain of surgery by general surgeons. There was no deformity to which the human family was subject that was more conspicuous, more distressing, more dreaded than cleft palate and hare-lip, and yet general surgeons had very largely passed it up. In operating for the correction of cleft palate and hare-lip the surgeon should so perform his operation as to leave the parts in just as nearly a normal condition as possible.

Arteriosclerosis of the Uterine Vessels.—Dr. JOHN W. PRICE of Louisville stated that a careful study of sections of this case was very suggestive that the hemorrhages were the result of rupture of diseased arterioles in the submucosa. The evidence in favor of this view was, first, the arterioles in the scubmucosa were sclerosed as well as the larger vessels. Second, there were areas beneath the submucosa containing recent hemorrhages undergoing fibrosis. Third, there were other areas beneath the submucosa which appeared to be old hemorrhages which had undergone fibrosis. Fourth, there was seen in other places outside the vessels evidence of repair. Fifth, a patient had a single profuse hemorrhage three years before operation, and had no unusual bleeding during the following two years. (A single ruptured uterine vessel would explain this hemorrhage as clearly as a case of hemiplegia could be explained by the rupture of a cerebral vessel. From the consideration of such a small number of cases we could not arrive at any conclusions, but it seemed to him worth while reporting his findings, as it might lead others who also had a small number of cases to report their's, and eventually a great mass of material would be accumulated from which conclusions might be drawn. Simpson had diagnosed the condition four times before operation. He was reasonably certain of the diagnosis in most of his cases. The history of the case, and the character of the hemorrhages, and the appearance of the patient were the greatest aid in making the diagnosis in the absence of finding a palpable tumor. In cases where there was any doubt as to whether there was present a cancer of the body of the uterus, he suggested the use of the curette or a hysterectomy. In cases where the bleeding had been as serious as in his case no time should be lost in curetting, the uterus should be removed as quickly as possible, and if found after removal to be malignant, then a more radical operation at once could be performed. All of his cases, except the last one, had been treated previously by palliative and so-called conservative methods, as had been the majority of cases reported. He felt that a continuance of a palliative treatment for too long a time subjected the patient to unnecessary danger, and if the patient was suffering with a malignant condition, much valuable time was lost.

Recent Results in the X-Ray Treatment of Menorrhagia, Dysmenorrhea, and Uterine Myoma. — Dr. SIDNEY LANGE of Cincinnati said the *x*-ray treatment of menorrhagia and uterine fibroids by the production of the artificial menopause had received a new impetus by the invention of the Coolidge tube. While results obtained by the use of the older style of tube were in a measure satisfactory, yet they were difficult and tedious to elicit and failures were common. If the proper technique was employed, the effect of Coolidge tube radiation upon the ovaries was the most certain of medical phenomena. The difficulty of selecting cases and excluding the possibility of malignancy was the only just criticism that could be directed against this method of therapy. The present paper was based upon fifty consecutive cases of menorrhagia, dysmenorrhea, and uterine fibroids treated by *x*-ray therapy. In every case a satisfactory result was achieved, an artificial menopause, apparently permanent, occurring in every case regardless of the age of the patient. These cases were referred from many different sources, and while only ordinary care and skill was employed in their selection malignancy had not developed in any case either during or following the treatment. In this series of fifty cases, nineteen were treated because of persistent menorrhagia. The ages of the patients varied from seventeen years to fifty years. The minimum *x*-radiation required to bring about a permanent menopause was one treatment (100 X) in a woman of fifty-nine. The greatest amount given any patient was 800 X (eight treatments) which was required to abolish the ovarian function in a girl of twenty. Another patient of seventeen years of age required 600 X (six treatments). A woman of thirty-two required 500 X. With increase in age of the patients the amount of *x*-radiation required to abolish the menstrual flow rapidly decreased. Thus patients around forty years required 500 X (five treatments), while between forty-five and fifty years 100 X to 400 X (one to four treatments) usually sufficed.

Dr. LEWIS S. MCMURTRY of Louisville stated that the use of the *x*-ray in treatment of diseases of the pelvic organs in women was new, but the present operative treatment of fibroid tumors of the uterus was the most successful of all operations known to surgery. The mortality from the surgical treatment was lower than that from any other major operation known to surgery, consequently there ought to be solid and substantial results from any treatment that was to take the place of the surgical treatment. In Kronig's cases the patients came for treatment a long time, and while the symptoms were ameliorated in those cases he saw under Kronig, the tumor had not disappeared.

Dr. CHANNING W. BARRETT of Chicago said, in sizing

up the cause of hemorrhage from the uterus, we should remember the uterus was an organ unlike other organs, in that it had a physiological hemorrhage, and any departure from that regular bleeding might be just a little change from the normal and the cause might be very slight. In weighing the different causes of hemorrhage we had to recognize that there was a material resistance to treatment due to a change in the blood vessels themselves. Oftentimes coming on at about the menopause, we should remember the uterus was a senile organ at that time. Instead of deciding that the uterus should come out if it was malignant, and ought to remain if it was not malignant, we should bear in mind that many of these uteri had to be removed at that time. With reference to the *x*-ray treatment outlined by Dr. Lange, he did no know that it would be satisfactory for those patients as regards hemorrhage ceasing because they had only been followed until the hemorrhage stopped. The method of dealing with fibroid tumors of the uterus by taking out the ovaries in aiming to bring about cessation of the menses and an early menopause had proved entirely satisfactory more than thirty or forty years ago, because there was a time in surgery when it was considered safe to take out the ovaries and decidedly dangerous to remove the uterus, and in that period of surgery the abdomen was opened and healthy ovaries removed in order that the diseased uterus might give less trouble. He did not believe the treatment which the doctor outlined would stand the test of time.

Dr. THOMAS J. WATKINS of Chicago said that as a remedy for temporary use in these cases, he would suggest an old but very efficient one, which consisted in packing the uterus with gauze saturated with iron, Monsell's solution or the tincture. The great advantage of this was that it was usually very efficient, and it was the only packing that could be left for a long time without becoming offensive. It could be left for a week without disturbing conditions or developing odors.

Dr. LANGE in closing stated that he did not offer this method of treatment for fibroid tumor of the uterus as a substitute for surgery, but for those cases that either refused operation or for those in which operation seemed inadvisable.

Kidney Lesions Diagnosed with the Aid of the Cystoscope and X-Ray.—Drs. COURTNEY W. SHROPSHIRE and CHARLES WATTERSON of Birmingham, Ala., said our exact knowledge concerning lesions of these structures would depend on two factors: (1) the cystoscopic examination, including functional test and uranalysis; (2) the *x*-ray examination. The cystoscopic examination and functional test, together with careful uranalysis was by far the most important. Next would come the radiographic examination, and then would be placed in line the physical findings and the patient's history. Within the past month in one of their hospitals a surgeon exposed the right ureter through its entire course in a search for stone which he was unable to find. The appendix was said to be diseased and was removed. No radiographic or cystoscopic examination was made or requested. Second: We would have errors of commission on the part of the cystoscopist due to lack of judgment in interpreting the results of his examination or to the failure of the radiologist to properly read his plate. They personally placed little faith on shadows said to be within the kidney or ureter unless they were shown positively to be within one of these structures by means of the shadow catheter, pelvic injection, or the stereoscopic plate. Pelvic injection, one of the most valuable means at our command for diagnosing lesions of the kidney, was vigorously attacked some years ago by members of the medical profession who had very bad results with its use, but since these results had been shown to be due to faulty technique this procedure was no longer in ill repute. It was, therefore, the duty of the cystoscopist to insist upon these procedures which were safe and painless when properly performed before having numerous *x*-ray plates made which were worthless even though the suspicious shadows were shown.

The Urogenital Tract in Routine Examination.—Dr. STANLEY G. ZINKE of Richmond, Ky., stated that one of the sources of trouble in the male which was most frequently overlooked was the prostate. He had read somewhere, he did not recall just where, that fully eighty per cent. of those who indulged in illicit sexual intercourse suffered from gonorrhea. This would mean that a little more than seventy per cent. of our male population contracted a urethritis of gonorrheal origin. Fully sixty per cent. of those who did so, suffered from an involvement of the posterior urethra. In other words, more than forty per cent. of men had, at some period during their lives a condition which, to say the least, was accompanied by prostatic involvement to a greater or lesser degree. This from gonorrhea alone. Let us say that twenty-five per cent. of these, which was a liberal allowance, received proper treatment. This left thirty per cent. who carried with them a gland which was pathological. Add to these ten per cent. for those whose prostate was abnormal from other causes, not hypertrophies or tumors, but masturbation, withdrawal, sexual excesses, ungratified desire, etc., and we had forty per cent. of the whole having prostates which needed attention. Modern methods of examination—cystoscopy, urethroscopy, ureteral catheterization, etc., had, in spite of their value, hindered, in many instances, in the making of a proper diagnosis.

Dr. BRANSFORD LEWIS of St. Louis said the general practitioner should familiarize himself with the cystoscope and the urethroscope, because the proper application of these instruments would enable him to make a correct diagnosis. He had known a number of patients who had gone on for many years suffering because they were told by general practitioners that their trouble was practically incurable, yet their condition could have been relieved promptly by simple operative measures.

Dr. F. M. BUCKMASTER of Effingham, Ill., said he recalled the case of a woman who was operated three times before the cause of her trouble was ascertained. She was about thirty years of age, and complained of recurrent attacks of pain, slightly continuous between times, along the lower end of the ureter in the appendical region. She also complained of attacks of cystitis. There was more or less urinary disturbance all the time, especially severe at times. The abdomen was opened and the appendix removed without relieving her symptoms. A year later, the symptoms continuing, the same surgeon opened the abdomen again, and removed a tube and ovary on that side. The cystitis and attacks continued. Three years after the first operation the symptoms not only continued but became worse, and at that time pus cells and blood cells were found in the urine, and the cystitis was quite severe a large part of the time. On investigation a stone was found located in the lower end of the left ureter. This stone was removed and the woman recovered.

Dr. LEON SOLOMON of Louisville said the fact that this subject was discussed at such a meeting as this was sufficient evidence, and made it plain, that it had a bearing for the general practitioner, so-called, as well as the surgeon and specialist. It was getting to be a difficult problem for the so-called internist to know where he stood in relation to the specialist and general surgeon. With reference to the *x*-ray, it might or might not disclose the nature of the trouble, and he felt sometimes it had been the cause of surgery which was difficult and might have been avoided. He had in mind a piece of surgery which was proposed by a careful diagnostician, himself an internist, an interpreter of the *x*-ray, where the positive finding of the operation was that of a stone in the ureter. It was demonstrated in advance of the operation by the catheter *in situ* that the shadows were phleboliths.

Dr. ZINKE said that in his paper he stated that if the general practitioner had a good knowledge of uranalysis and of symptoms in connection with a good personal history, it would at least lead him on the right track if it did not give him a clue to the condition present. What was the use, for instance, of Dr. Lewis practising his specialty if all the general practitioners could make as accurate a diagnosis as he did?

Limitations of High-Frequency Treatment of Papilloma of the Bladder.—Dr. H. G. HAMER of Indianapolis said applications of the high frequency current in these cases of carcinoma showed some hemostatic effect and slight reduction in the size of tumor or, on the other hand, marked reduction in size to be followed by rapid growth uncontrolled by burning. In one case it seemed to cause more rapid extension. He formulated the following conclusions: (1) High frequency cauterization was an important addition to our means of attacking vesical papillomata of the non infiltrating type. (2) All benign papillomata should be treated primarily with the high frequency current in view of the high percentage of recurrences following open operation (50 per cent.) and the high mortality (10 per cent.). (3) In cases where suprapubic operations had been done recurrences should be looked for and, if present, treated by fulguration upon their first appearance. (4) In

dealing with papilloma involving the vesical orifice and prostatic urethra, perineal cystotomy with removal of as much of the tumor as possible, and application of the high frequency current to the remaining growth seemed a rational procedure.

Dr. JOHN R. CAULK of St. Louis said the general practitioner should consider any bleeding from the urinary tract as serious, particularly a symptomless hematuria, and not stamp these hemorrhages as due to a congested bladder neck, and various other things that were so commonly ascribed as causative factors in these cases. The general surgeon had yet to be convinced of the importance of the cystoscope in almost all cases of prostatic hypertrophy before operation. Patients should be cystoscoped because of the fact that tumors quite frequently were back of prostatic obstructions and many of the untoward results following perineal prostatectomy seemed to be due to leaving behind a tumor which was back of the obstruction. He had seen four such cases.

(*To be continued.*)

FIRST DISTRICT BRANCH OF THE MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Ninth Annual Meeting, Held in Nyack, October 9, 1915.

THE PRESIDENT, DR. JAMES E. SADLIER OF POUGHKEEPSIE, IN THE CHAIR.

President's Address—The Utilization of the Knowledge We Possess.—Dr. JAMES E. SADLIER of Poughkeepsie delivered this address, in which he said that it was the generally accepted view that medicine was not an exact science, and possibly might never be such, yet he was firmly convinced that the members of the medical profession devoted more time to study, observation and thought, and were more thoroughly educated along the lines of their professional work than were the members of other great professions. Very much of the knowledge now possessed by the profession of medicine was exact in character, and while it might be elaborated and amplified in the future, the present basic principles would ever remain. Dr. Sadlier said that he was convinced that as the result of strenuous work, exhaustive in character and for other reasons, they at times failed to be practical, and went looking for some "Will-o'-the-Wisp" or Sunday disease, when if they would utilize their knowledge and judgment they could easily recognize a week-day condition, one of known and established characteristics. In illustration of this the essayist cited the frequency with which empyema was overlooked for a time, or a diagnosis made by a consulting physician that should have been determined by the physician in attendance had he but considered the possibility and weighed carefully the history and clinical findings. Cancer was another condition which they should be alert and watchful to detect, being not unmindful of the fact that chronic irritation, in all its varied types and locations, was an established predisposing element. The need should be constantly kept in mind of treating radically and early all lacerations of the female generative organs, the benign tumors, gastric ulcers, gall stones, and infective and irritative conditions about the mouth, and thereby utilizing to its known limits our present knowledge upon this subject. He emphasized the necessity of abandoning all efforts at "watchful waiting" which would lull the patient to destruction and recommended the adoption of the principle of complete eradication through surgical interference. If one lacked the ability to absolutely diagnose sufficiently early a cancer of the stomach he could establish a diagnosis of some condition of a surgical nature in time to permit of operative interference of an exploratory character. After referring to the damage that was likely to result from lack of attention to focal sources of infection, Dr. Sadlier said he was convinced that in their endeavor to diagnose many diseases, especially those of an abdominal or pelvic character, they failed, not because of lack of knowledge but from neglect to avail themselves of the advantage to be obtained from taking a proper history and carefully reviewing all the symptoms and conditions in the patient leading to his present state. Such history should be written and could seldom be obtained at one sitting and frequently required great patience and astuteness on the part of the historian. In the diagnosis of abdominal disease the *x*-ray should be utilized simply as one link in the chain of evidence, since strict reliance upon it was frequently misleading. In the acute infections, perforations, and obsructions of the organs of the abdominal and pelvic cavities they were not always practical and scientific in their pre-operative treatment; fractured bones were always put at rest immediately by temporary or permanent splinting, but acute conditions below the diaphragm were too frequently mobilized by cathartics, the result of which was to disseminate the infection and prevent localization of the disease. In these conditions rest meant freedom from all things which excited peristalsis or any muscular movement and at times the patient should be placed in such a position as would tend to localize the infective process. After speaking of the need of proper mental and physical post-operative treatment in surgical cases, Dr. Sadlier dwelt on the important part played by good nursing in the mitigation and elimination of diseased conditions. While this nursing care was exercised to its fullest extent in hospitals and to a fairly adequate degree in the homes in cities in rural districts it was not taken advantage of. In obstetric practice they were not fully executing their proper present day knowledge. They were not always caring for these patients from the aseptic standpoint as they would for a surgical case. Here asepsis could only be carried out by having the services of a professional nurse. Too much of this care was left to unskilled, careless people. It was high time that they looked to basic fundamental principles of obstetrics and insisted upon proper ante-partum and post-partum care, sufficient attention to pelvimetry and a complete knowledge of the case prior to labor, as well as proper care and environment during childbirth and the period following. The fact that the surgical treatment of disease seemed to have a continuously increasing sphere of usefulness did not eliminate the medical man from the case or lessen the great responsibility he assumed in interpreting the symptomatology and physical findings that he might be able to get timely and adequate surgery performed, for most cases were seen primarily by the family physician and upon him devolved the responsibility of suggesting surgical consultations. That the medical man might meet this responsibility it was imperative that he should familiarize himself with surgical pathology and wherever possible should compare the results of physical examination and the symtomatology of the case with the finding s as seen at operation.

Address by the President of the Medical Society of the State of New York.—Dr. W. STANTON GLEASON of Newburgh delivered this address. He said that the Medical Society of the State of New York was now one hundred and nine years old, and from the present standpoint the founders of the organization had builded better than they knew. Each year added strength to the organization and the names who took part in this upbuilding, figuratively speaking, made the hall of fame of this organization. In speaking of the government of the society, Dr. Gleason said that plan of representation in the governing body, grouped in the house of delegates, gave a voice to all and made the vote of the majority paramount. Varying suggestions had arisen from year to year as to changes in the by-laws, but that which was good had remained and that which was bad had been eliminated. To-day, after an experience of three and one-half years as a member of the council, one year as president of the First District Branch, two years a vice-president of the State Society, and six months as president, he felt that it was better to conserve that which was good than to attempt an untried course and possibly break down that which had been so well builded. Therefore it would be his endeavor to follow a conservative course. Dr. Gleason then spoke of certain matters which might affect them as members of the State Society and as practitioners, emphasizing their responsibilities to attend the meetings of their county societies and to fulfill their obligations to the county, district, and State Society as solemnly as they did other obligations in daily life. The best men socially and intellectually found time and pleasure in supporting in every sense by their presence and activity their medical social obligations. After referring to the progress of medical education during the past twenty-five years and reviewing the advance that had been made in medicine and surgery in recent years, the speaker pointed out that these things had been due almost entirely to the efforts of medical men, that philanthropists with but few exceptions had not helped medical education. Practically all that had been accomplished had been consummated by the strenuous efforts of the best minds in the medical profession.

State aid was now being extended to medical education through State universities in nearly all the States of the Union and it was to be hoped that in a few years every State in this country would join in giving aid to the cause of medical education. Medical men appreciated fully what had been accomplished but he feared the public at large did not. There was a growing disregard for the guarding and guiding influences that medicine so long held in a protecting sense over public thought and sentiment. In this attitude the public was not wholly at fault. Some thirty years ago several medical leaders in medical thought avowed through the medium of the medical journals their pessimism and almost nihilism in reference to the efficiency of drugs. These ideas made a widespread impression, not only upon medical minds but deeply impressed the layman. This was the entering wedge into the solidarity of medical influence that had paved the way for various "pathies" and "practors," and the horizon was thick with incoming phalanxes of "isms." Another influence which they must take home to themselves as general practitioners was the effect of the personal element in the treatment of disease. When a patient appeared they used all possible aids in making a physical diagnosis, but where they frequently failed was in not considering the mental attitude of the patient. One should make as complete a mental analysis of his patient's symptoms from a psychological standpoint as he did from a physical basis. Fully ten per cent of those coming to the physician's office for relief from an indefinite trouble suffered from neurasthenia to a greater or lesser degree, and this was the type of patient that floated from their offices to the various cults. One did not need to descend to the occult in the treatment of disease, but he should make himself broad enough to consider both the physical and mental in arriving at a diagnosis. Then again they should endeavor through every legitimate means to enlighten the lay mind on things medical. In closing, Dr. Gleason recommended that as economic problems were of growing importance to the general practitioner, the county medical societies should devote one meeting a year to some feature of medical economics, not only as to their methods, but as to the best means of solving our economic problems, and that each county society should have a legislative committee which would work in full accord with the central committee of the State Society. In this way they might keep themselves constantly informed and could use such influences as would redound to the good of the medical profession and the public at large. A paid lobbyist was not what they needed; it was for them to uphold the dignity, the character and the influences of a noble and dignified profession.

What Are the Indications for Removal of a Section for Microscopical Diagnosis in Suspected Malignancy?—Dr. SAMUEL E. GETTY of Yonkers read this paper. He stated that while the statistical reports of the large clinics were showing much better results in their cancer cases during the past ten years, due probably to having patients referred to them at an earlier stage of the disease and to a more thorough and perfect technique, there was still room for improvement in seeing the patients earlier. The physician was often confronted with a condition in which he had to decide the question of malignancy. In arriving at a decision the history of the patient should be gone into very carefully and a thorough examination made; if the diagnosis was not fairly complete recourse was had to a section taken from the growth for microscopical examination. It was by such preliminary examination that they often lost out, for valuable time was lost and by the preliminary operation the lymphatics were opened and it became possible for the cancer cells to make an excursion, and in this way a case that would have given a very hopeful prognosis was transformed into one which was much less favorable. There was no doubt but that the ideal condition was to have an expert pathologist at hand during the preliminary operation to make an immediate examination, but really expert pathologists were rare and were not available in the smaller cities. Again the question arose whether it was safe to trust an immediate examination which might not be entirely reliable, since such an examination was made hurriedly and there were always chances of error, and in the minds of good surgeons it was not considered final. In the opinion of the essayist, after a careful consideration of the history of the case in conjunction with the physical findings, using all methods except cutting, the probable diagnosis of malignancy was made, the correct advice to the patient was the operation one would perform if the condition were positively diagnosed as malignant. If this advice was accepted, the operation pereformed, the specimen thoroughly examined by a tissue expert, and malignancy was found to be present, the surgeon had the satisfaction of having done his patient a good turn; if the tissue removed was in the pre-cancerous stage he still had the satisfaction of having done the patient a good turn, and if the tissue was non-malignant the worst he had done was to have performed a needless operation; yet who could say that this same tissue might not have gone through the changes ending in a maliganancy if left *in situ*. It was better to perform an occasional needless operation rather than by a preliminary operation to run the risk of spreading cancer cells. The necessity for a preliminary section would seldom arise if the history of each case was checked up with the patholigical report of the specimen removed, for the surgeon would become more and more expert in diagnosis as his experience increased. They should rigidly observe the maxim, "Cut around, but never into a suspected cancer." If this advice were followed the results of surgical operations for cancer would show fewer returns of the growth.

Melanotic Sarcoma.—Dr. J. P. HOGUET of New York presented this paper, which he prefaced by stating that he was visiting the district branch societies in the interest of the propaganda department of the National Association for the Control of Cancer. He said that they were all familiar with the more common forms of cancer and recognized the necessity for early diagnosis and early surgical intervention, and hence he had chosen one of the rarer forms of malignant disease for consideration at this time. Melanotic sarcoma was easily recognizable when it had once developed, but, by that time, owing to the rapidity with which the malignant process progressed, surgical intervention was seldom effective. This form of malignancy usually had its origin in a pigmented mole and if the development of a serious condition was to be avoided, the only safe course to pursue was to remove every pigmented mole that was subject to irriation or showed any signs suggestive of pathological change. In melanotic sarcoma, after ulceration had once taken place the pathological process spread so rapidly that surgical intervention was futile. Operations on well-developed melanotic sarcoma were followed by recurrence in practically every instance.

Dr. PARKER SYMS of New York said that the fact was they did not know what cancer was. The cancer cell seemed to be distinguished from the perfectly normal cell only by the unruly production of perfect cells, and so far as was known a growth did not become malignant until its cells penetrated the basement membrane. What they had learned about cancer had been learned in clinical ways. In this way they had learned that carcinoma in its early stages was a purely local condition and if they entirely removed the growth they could effect a cure. Indeed it might be assumed that under the ideal condition of getting the case in an early stage 100 per cent of cures might be effected. Dr. Hoguet had referred to the work of the National Association for the Control of Cancer and it was a significant fact that the campaign for the dissemination of knowledge in the preventing of cancer was originated in the same way as that against tuberculosis. It was a striking fact that the knowledge possessed by the medical profession had lain dormant until the subject was brought up by a layman. Dr. Keen, in 1900, was one of the pioneers in urging upon physicians a greater watchfulness in detecting cancer in its early stages and he read a paper advising the removal of pigmented moles during their stage of non-maligancy. Dr. Bloodgood followed him in calling attention to the dangers of pigmented moles becoming malignant and then others directed attention to this possibility. Bloodgood tabulated 65 cases in which malignant transformation had taken place in pigmented moles and all resulted in death either from local recurrence or from metastases. In 79 or 80 cases in which pigmented moles were removed before they became malignant there were no untoward results. One could not tell how many of these might have become malignant. The pigmented mole was a precancerous or sarcomatous condition and if removal was effected during the precancerous stage malignancy could be prevented. Dr. Getty had brought up an important question and one upon which the profession were not united. They had been taught that in a case in which cancer was sus-

pected they should take a section for examination. Dr. Bloodgood said that he did not know of a single case in which a preliminary operation had been done and then a subsequent operation performed in which recurrence had not taken place. Cutting liberated the cancer elements, disseminated them, and made incurable what would otherwise have been a favorable case. They were now seeing cases earlier than formerly and this brought up new problems with reference to diagnosis and operation. The Pennsylvania Commission for the Investigation of Cancer reported that fourteen months on an average elapsed after the presence of a breast tumor was noticed before recourse to operation was had, so that while these cases were not seen in the last stages of cancer they were seen in a late stage. Popular education, however, was bringing these cases to the physician earlier than formerly, and hence a surgical diagnosis was not as easy as formerly. It should be remembered, however, that points of irritation were in an abnormal condition and might result in cancer. Furthermore it was conceded that diagnosis should be made at the time of operation. One read that the Mayo's relied on a frozen section examination and had no reason to regret it, but one also learned on reading further that in early mastitis as many as thirty sections were examined before deciding upon the diagnosis, so that if one relied upon an immediate examination at the time of operation the chances would be thirty to one that a wrong diagnosis might be reached. Dr. Ewing of New York would not make a diagnosis at all from a frozen section.

Dr. Wisner R. Townsend of New York said this subject was interesting to him not only from the personal standpoint but from the standpoint of the State Society. It would be remembered that when the campaig against tuberculosis was started the State Society resented it, stating that the health boards were invading the rights of private physicians. The campaign against cancer was not only not opposed by the State Society but they were doing what they could to further it. It was most encouraging to see the State Society take up something in a constructive way, and he was gratified to hear Dr. Getty's paper because it represented the unanimous views of all who have spoken authoritatively on this subject. As illustrating the effect of the campaign for publicity, Dr. Townsend related that a physician up-State had told him that he had been consulted by two women in one day because of what they had read in a lay publication with reference to the early signs of cancer. Dr. Gaylord of the Buffalo Cancer Hospital had told him that he was now receiving ten to fifteen specimens a day for examination, whereas in years past he had received but one or two. He also stated that they were now getting specimens in an earlier stage than formerly. Dr. Townsend said he had always had the highest respect for the ability of the country practitioner and believed he was the best man they had in the profession. It was he who must make an early diagnosis of cancer and must insist that if there was a tumor in the breast of a female it must be removed. As to the campaign against cancer the work going on throughout the State was reassuring. The number of papers on the subject of cancer read throughout the State during the past three weeks exceeded the number read during the last ten years.

Dr. George A. Leitner of Piermont said they had directed their attention to the need of early operation in tumors of the breast, but he wished to call attention to early carcinoma of the stomach. The surgeon was receiving many cases of carcinoma of the stomach too late to do any good. The medical man was likely to treat early cases of carcinoma as simply cases of indigestion, whereas he should resort to the *x*-ray and other methods for the diagnosis of early carcinoma of the stomach. Every so-called case of dyspepsia lasting over three months should be referred to the surgeon for diagnosis, since early diagnosis and early operation offered the only hope in carcinoma of the pylorus or stomach.

Dr. S. Oscar Meyers of Mount Vernon said that while the general practitioner had not been directly charged with negligence in diagnosing early cancer or delay in advising operation, there was an atmosphere of implied criticism of the general practitioner for the so-called neglected cases of cancer. As a general practitioner he wished to disclaim blame. The practitioner frequently after examining a case advised operation, but the patient, disliking the idea of an operation, went off to try electrotherapeutics, chiropractics, etc., and thus the general practitioner was put in the wrong when it was the fault of the patient and the various "pathies."

Dr. James E. Sadlier of Poughkeepsie said he could not let this occasion go by without emphasizing the folly of cutting into things, the exact nature of which they did not know, for the purpose of getting a specimen. He also emphasized the possibility of mistake in examination of the frozen section and said that the surgeon should become familiar with the microscopical appearance of cancer so that he could arrive at a correct diagnosis at the time of operation. Dr. Getty had sounded a warning that should be impressed upon their minds, that the practice of operating for a specimen and then operating later was most reprehensible.

Dr. J. P. Hoguet of New York said that as to the question whether every pigmented mole should be removed, that the removal of every pigmented mole was of course impossible, but that every pigmented mole that was subjected to traumatism or irritation should be removed before ulceration occurred, because very soon after ulceration took place the glands became involved and interference was then ineffective.

The Importance of the Early Recognition of Arteriosclerosis.—Dr. Louis Faugeres Bishop of New York presented this communication in which he said that the definition of arteriosclerosis in the minds of most people involved the presence of palpable physical changes in the blood vessels, with accompanying changes in the heart and other organs. In his work Dr. Bishop defined arteriosclerosis as a disease consisting of a disturbance of metabolism, meaning a disturbance of the physiology of individual cells, leading eventually to changes in the heart, blood vessels, kidneys and other organs. Thus arteriosclerosis seemed to him rather a question of pathological physiology than pathological anatomy. The importance of discovering arteriosclerosis was very great at all stages, but it would be particularly valuable if it could be recognized before permanent structural damage had taken place. It seemed to the essayist that the real origin of arteriosclerosis was a change in the relation of the cells to proteins, analogous to a sensitization such as was the basis of other anaphylactic phenomena. The causes for this change were found in what Dr. Crile had defined as the "kinetic drive." The individual was subjected to some sensitizing event, such as a severe infection, a period of great anxiety, or poisoning by some foreign protein. From the definition of the condition under consideration it was evident that the present means of detecting arteriosclerosis in its early stages were not adequate, but a person who had given long and continued thought to this matter was able to do so, just as after a prolonged examination a man of experience could form a definite opinion as to whether an individual was insane or not. It was twice as important that one should recognize arteriosclerosis now as in former times when people lived differently because during the last thirty years the number of victims of this condition had increased in the ratio of two to one. The importance of metabolism was seldom thoroughly appreciated. Upon an early appreciation of its relation to cardiovascular-renal disease depended the prevention and treatment of these conditions. First there was a general disorder of the cells of the entire body, without special localization; later some particular organ suffered sufficiently to give symptoms. If it was the heart one called it "heart disease"; if the kidneys, "kidney disease," and so on. It was not easy to make clear the distinction between arteriosclerosis, the disease, and arteriosclerosis, the lesion. Advances in our knowledge of biochemistry had made it plain that it was the qualitative relations of the protein that were important rather than the quantitative. The minuteness of the quantity of a particular food that could keep up the irritation of the cells in a person who was sensitive and continue the process of the development of arteriosclerosis was surprising. If a person was under stress of worry and diseases which were liable to render him sensitive to certain particular proteins, then was the time when careful dietetics should be instituted. The earliest symptoms of arteriosclerosis were coincident with the earliest symptoms of disturbance of metabolism, such as "biliousness," sick-headaches and intestinal fermentation. One of the earliest symptoms of the disease was discomfort in the front of the chest on exertion after eating; the next early sign was disturbance of the blood pressure, usually a tendency to high pressure, but sometimes the depressor poisons were in the ascendency. At this stage proper dietetic, hygienic, and medical treatment could very often arrest the disease entirely and restore the patient to health. At a

later stage, a checking of the process and a continuation of life and strength could be accomplished only by a continuous and strict regimen.

Dr. S. W. S. Toms of Nyack said that this condition, which one found in men and women of from fifty to fifty-five years of age, showing chest oppression after eating and especially after eating heartily, was one frequently seen in the Nyack commuter. Hurried breakfast and lunch and climbing a hill to reach home in an exhausted condition after the day's work seemed to be the cause. One found these patients with a blood pressure of from 145 to 220, irregular bowels, and more or less disturbed sleep. The physician might tell them how to regulate their lives, but the advice was not effective, because they did not follow it. It would be interesting to know how Dr. Bishop succeeded in persuading his patients to regulate their mode of life so as to get the desired results.

Dr. May Dunning Rose of New York said she would like to ask Dr. Bishop whether he had ever made a study as to the effect of the disturbance of the mineral balance in the diet upon arteriosclerosis. It was well known that in modern methods of cooking the mineral salts, especially the potassium salts, were readily dissolved and were thrown out. There was likewise a deficiency of mineral salts in white bread and granulated sugar, and it would be interesting to know what effect this deficiency of mineral salts had upon the development of arteriosclerosis.

Dr. Bishop said that in the question of diet it was his practice to cut off eggs, fish, and meat in patients with the conditions under discussion and to supply all proteins with cheese and milk, later adding chicken. If the patient took this well he then allowed eggs or lamb. He believed that the protein disturbance was qualitative and not quantitative. A low protein diet did not help but a protein free diet did help. Dr. Bishop said he was aware that Mr. McCann was an advocate of the mineral stavation theory but that in his opinion the quantity of mineral present in an ordinary diet was so much in excess of the metabolic needs of the body that it would be difficult to reduce it to a point where the result would be mineral starvation. The point brought out as to the appearance of the eye as an early indication of arteriosclerosis was well taken, but one did not necessarily need an ophthalmoscope to detect it. Dr. Draper many years ago had called attention to the shininess of the conjunctiva as an early sign of arteriosclerosis, but of course with the ophthalmoscope one could see much more. Many eye men did not take a hemorrhage of the retina as a serious matter, but when this condition was present he gave the patient a life expectation of about three years; however, with a strict dietic regimen it might possibly be six or seven years.

Hematuria: Its Clinical Significance.—Dr. Edward C. Thompson of Newburgh read this paper, in which he stated that it had been his surgical experience that the general profession had not been awake to the serious significance of renal hematuria, or rather had been slow to avail themselves of the more refined laboratory methods by which alone accuracy and diagnosis could be made. Not only was the general practitioner to be admonished in the matter of early renal diagnosis but a restraining hand should often stay the surgeon's scalpel. Hematuria did not necessarily mean a stone in the kidney, nor did a certain amount of operative skill mean a good surgeon. Renal hematuria should be borne in mind, whether existing alone or part of a symptom complex, not as pathognomonic of any disease, but as possibly a symptom of serious disease. A diagnosis of renal hematuria meant, of course, the exclusion of the urethra, the bladder, and the ureter, and was only positively made by the use of the cystoscope. Having proven a case to be one of renal hematuria, non-surgical conditions such as parasites, hemophilia and malignant types of certain infectious diseases, effects of certain drugs, acute nephritis, acute congestion of the kidney, chronic nephritis and hemorrhage due to severe muscular exercise or to tabes dorsalis must be excluded. Occasionally a movable kidney and hydronephrosis might be a cause of hematuria. Acute and chronic infections of the kidneys were often associated with hematuria. In the acute cases chills, fever, pain, and pus in the urine usually made clear the diagnosis. Occasionally in the insidious cases of pyelitis unassociated with the usual symptoms of infection hematura might be the only and therefore a perplexing symptom. A bleeding kidney without other symptoms might be the first sign of tuberculosis, neoplasm, or renal varix. To make the diagnosis of essential hematuria a hematuria must be more or less profuse, more or less constant, and without clinical symptoms except those consistent with hematuria. If, however, with the hematuria there was a highly acid urine, a slight polyuria, and an occasional afternoon temperature, tuberculosis was to be suspected. Yet all these symptoms might be absent and still the case be one of tuberculosis of the kidney. If there was any suspicion of the case, the inoculation of a guinea-pig with the patient's urine should not be neglected. A single hemorrhage of the kidney occurring in a child or an adult past middle life should be looked upon with grave suspicion. The bleeding from a renal varix very closely simulated essential hematuria. The essayist related the history of a case which he believed to be renal varix in which he believed the complete longitudinal bisections of the kidney with cutting of the venous radicals effected a cure. This case was also interesting from the fact that there was intense pain on the right side, while the cystoscope showed the bleeding from the left kidney. This was a point to be remembered in the diagnosis of kidney disease. The treatment of renal hematuria depended upon the exciting cause. In essential hematuria, if one assumed that a normal kidney might bleed, the tendency would be to treat the case conservatively; but if one believed that most, if not all, such kidneys had some pathological condition one might be somewhat more radical. It was true that most of them got well as the result of nephrotomy or nephrectomy, and it was also true that many got well without operation or any treatment. The usual methods of irritating the kidney pelvis had been rather unsatisfactory and it seemed that all bleeding at all persistent or profuse and not yielding to treatment would warrant an exploratory operation.

Dr. Edward C. Rushmore of Tuxedo called attention to the necessity of distinguishing between microscopical and macroscopical bleeding. The bleeding in many cases could only be detected by the microscope. The cases in which the bleeding was macroscopical were largely surgical conditions. He emphasized the importance of an early recognition of tuberculosis of the kidney and of the advisability of resorting to guinea-pig inoculation in every case in which there was the slightest suspicion of that condition, and also the advisability of having expert advice. A medical paper was needed describing the exact method that the practitioner could take to make a diagnosis of these kidney conditions in a short time.

Practical Deductions to Be Derived from Examination of the Blood.—Dr. Howard P. Carpenter of Poughkeepsie read this paper in which he drew attention to some of the commonly overlooked blood pictures in various conditions, as for instance when an acute appendix was in a seemingly quiescent period and examination of the blood showed perhaps 24,000 leucocytes and 95 per cent. polymorphonuclears with no eosinophiles. This did not mean that because the patient was more comfortable that operation should be postponed a day or so to see what developed; it meant to operate at once before this appendix filled with pus and ruptured into the abdomen. Again the differential point between pernicious anemia and other anemias was its tendency to progress to a fatal issue. This clinical behavior rather than a blood examination alone was necessary for the diagnosis of pernicious anemia. There were few pathological conditions upon which a leucocyte count did not throw some light, but the bare count without the differential was worse than none at all. By experience it had been learned that a pus condition was to be expected when the polynuclear count hovered around 90 per cent, even if the leucocytes as a whole were not increased. In some cases in which the patient was not reacting well to an infection there was sometimes little leucocytosis but such cases were sometimes found to have a differential count as high as 99 per cent. polynuclears. Associated with the increase of polynuclear leucocytes in the pyogenic infections there was always a diminution or absence of eosinophiles which was designated by Simon as "septic factor." As the infection was being successfully overcome the eosinophiles would return. The diminution of leucocytes in malaria was an aid not to be neglected, for it was sometimes difficult to find the malarial parasites. In a case coming under the observation of the essayist an intermittent hematuria brought up the question as to whether the condition was malaria or an infected kidney. The blood examination showed 5000 leucocytes and over 60 per cent lymphocytes. This was evidence that the case was malaria, and a more persistent search revealed the

plasmodium. An increase of leucocytes of 15,000 to 20,000 might occur within an hour after an extensive acute hemorrhage, too quickly to be due to infection. Leukemia was one condition that could be diagnosed from an examination of the blood alone, the leucocytes being enormously increased, sometimes to two or three hundred thousand with a predominance of lymphocytes in the lymphatic variety and of myelocytes in the splenomyelogenous variety. Children had a large proportion of lymphocytes and a higher total count than adults, a fact that should be borne in mind. The finding of nucleated red cells even in quite considerable numbers in blood smears was insufficient evidence upon which to base a diagnosis of pernicious anemia. If the majority of nucleated red cells were megaloblasts then other symptoms of pernicious anemia should be sought. The laboratory worker was probably discredited more times in the performance of the Widal test for typhoid fever than in any other one procedure. Many errors might be prevented if specimens sent to the laboratory were collected in capillary tubes instead of on glass, paper or metal slides. The Widal reaction usually appeared in the second week of the disease, but sometimes not until the third or fourth week or well into convalescence. A reaction often persisted for months or even for years after an attack of typhoid fever, thus making a history of much importance in the proper interpretation of a positive Widal. The essayist considered somewhat at length the significance of the Wasserman test for syphilis and stated that the proper attitude to take was that this test was of only secondary importance to a complete study of a case of syphilis. Kaplan's view that the serologist should report no serum positive unless it had resisted the best legitimate efforts to make it negative was excellent advice. However carefully a blood examination had been performed in all conditions its results were to be interpreted only in the light of the fullest possible clinical information.

Traumatic Hysteria: Trauma, Cause of Occasion.— Dr. DANIEL B. HARDENBURGH of Middletown read this paper (see page 824).

Report upon a Case of Surgery of the Liver. — Dr. GEORGE A. LEITNER of Piermont presented this paper. After briefly reviewing the traumatic and pathological conditions calling for radical interference and the results to be expected from such surgical operations, he related a case which was interesting because of its pathology and unique because only one other case of similar operation with complete recovery had been reported. Dr. W. W. Keen of Philadelphia had also successfully removed the entire left lobe of the liver. The patient was an Italian woman, thirty-three years of age, the mother of three children, the youngest seven months old. Some months after her last delivery she complained at intervals of severe spasmodic pain in the abdomen. Physical examination revealed a movable mass as large as a cocoanut located behind the umbilicus, somewhat toward the right iliac fossa and resting on the crest of the pubes and Poupart's ligament. The tumor could be seen distinctly, was dull on percussion, and gave a distinct fluctuating sensation. A diagnosis of probable ovarian cyst was made, although *per vaginam* the mass could not be felt. The patient entered the Nyack Hospital on January 3, 1915, and was operated upon on the following day by Dr. Leitner, assisted by Dr. Blauvelt and Dr. Toms. A free incision from the umbilicus to the crest of the pubes through the median line was made and a dark blue tumor presented itself within the abdominal cavity. The tumor refused to be delivered and a search for the pedicle showed that it was not attached to any organ in the pelvic cavity, but that it was attached to the summit of the mass. By following the pedicle it was found attached to the under surface of the liver. A diagnosis of tumor of the liver, a probable hydatid cyst, was then made. The lower incision was carefully closed and a second incision made from the ensiform cartilage to the umbilicus. By the aid of retractors and the walling off of the stomach and intestine with hot pads, the tumor with its relation to the surrounding organs was clearly seen. The left lobe of the liver was missing and they concluded at once that they were dealing with a tumor of the left lobe. The pedicle was between four and five inches in width, its thickness varying from about one and one-half inches at its right border to a thin narrow strip of peritoneum at the left or splenic border. The length of the pedicle was about five inches. The method of removal was as follows: Two broad ligament clamps above and two below were employed to grasp the pedicle at right angles to its long axis, leaving a space of about two inches between the upper and lower clamps. Sufficient pressure was made to compress this fragile tissue without crushing or lacerating it too violently. The tumor was then removed by cutting close to the lower clamp with scissors, leaving a prominent stump which was cauterized by the Paquelin cautery. The stump with the two clamps still in position was sutured with No. 3 catgut, using two needles and ordinary harnessmaker's suture. The abdominal wall was closed in the usual manner. The two clamps were allowed to remain attached to the stump, the handles being brought out through the upper angle of the wound. No drainage was instituted in this case. The following day there was a slight rise in temperature and pulse rate. At the end of five days the patient had reached a normal condition, when she was again taken to the operating room, ether administered, and preparations made for the rapid opening of the abdomen in case of hemorrhage. The clamps were slowly released and removed. There was no bleeding, and after careful watching for fifteen minutes the openings left by the clamps were closed. The patient left the hospital on February 3 and had since enjoyed excellent health. Dr. John H. Larkin, who made the pathological examination had manifested a keen interest in this specimen and wrote that this type of tumor belonged really in the borderland cases between regeneration on the one hand and tumor formation on the other. However, it was his opinion that it represented a type of extreme regeneration, secondary hemorrhage having occurred in the central part. Practically no liver tissue remained, the whole mass being made up of an indefinite amount of cuboidal epithelial cells, with a tendency to reform.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

EMERGENCY SURGERY. By JOHN W. SLUSS. Published by P. Blakiston's Son & Co., 1012 Walnut St., Philadelphia, Pa. Third edition, revised and enlarged, with 685 illustrations, some of which are printed in colors; 832 pages. Price, $4.00 net.

REPORT OF THE BUREAU OF HEALTH FOR THE PHILIPPINE ISLANDS for the fiscal year from January 1 to December 31, 1914. By VICTOR G. HEISER, M.D., Director of Health; Surgeon, United States Public Health Service, Manila, Bureau of Printing, 1915.

MEMORIAL ADDRESSES AND RESOLUTIONS. By S. WEIR MITCHELL. Published by Wm. J. Dornan, printer, Philadelphia; 155 pages.

NEUE UNTERSUCHUNGEN ÜBER FLEISCHEXTRAKT. Von Von Dr. LEBBIN. Published by August Hirschwald; 64 pages. Price M. 1.60.

INFANT HEALTH. By J. (SHAWNET) CAMERON MACMILLAN. Published by Oxford University Press, Warwick Square, E. C. London, (American branch) 29-35 West Thirty-second St., New York; 128 pages. Price, 75 cents.

THE PRACTITIONER'S ENCYCLOPEDIA OF MEDICAL TREATMENT. Edited by W. LANGDON BROWN, M.D., and J. KEOGH MURPHY, M.C., with an introduction by Sir Thomas Clifford Allbutt. Published by Oxford University Press, 35 West Thirty-second St., New York; 874 pages. Price, $8.00.

DISEASES OF NUTRITION AND INFANT FEEDING. By JOHN LOVETT MORSE and FRITZ B. TALBOT. Published by the Macmillan Company, 66 Fifth Ave., New York; 346 pages. Price, $2.50.

ORTHOPEDIC SURGERY. By EDWARD H. BRADFORD and ROBERT W. LOVETT. Published by William Wood & Company, New York. Fifth edition, profusely illustrated; 416 pages. Price, $3.75 net.

TEXT-BOOK OF NERVOUS DISEASES. By CHAS. L. DANA. Published by William Wood & Company. Eighth edition, with 262 illustrations, including four plates in black and color; 632 pages. Price, $4.25.

DISEASES OF INFANTS AND CHILDREN. By HENRY DWIGHT CHAPIN and GODFREY ROGER PISEK. Published by William Wood & Company. Third revised edition, with 179 cuts and 12 colored plates; 578 pages. Price, $3.25 net.

THE PROGNOSIS IN CARDIOVASCULAR DISEASES.

BY THOMAS E. SATTERTHWAITE, M.D., LL.D., Sc.D.,

NEW YORK.

PROGNOSIS in its proper sense covers the possibility of recovery, whether complete or partial, temporary, or permanent; the duration of the disease; and the expectation of life. On the broad lines of classification which are generally adopted there is a fair degree of unanimity as to the future of cardiovascular diseases, yet in every variety there are contingencies which can be neither foreseen nor controlled.

For instance, in the valvular forms the state of the vessels has an important bearing on the forecast, which is also influenced by the nature and extent of the lesion, the number of valves implicated, and the patient's age, sex, constitution, and other factors whose name is legion. In the face of such facts a definite prognosis is always difficult and often uncertain. We usually have to be satisfied with conclusions of a general nature and figures that are approximate. It is true that in some affections a prognosis can be made with a fair degree of accuracy, but in the majority it is not so. We are making progress in this matter, however, for we know how under favoring conditions the danger to life may be minimized, or the end hastened by untoward events.

The most important points bearing on the prognosis are the character of the disease, whether acute or chronic, functional or organic, benign or malignant; its location, variety, extent, duration, and complications; the degree to which the myocardium is implicated, and the efficiency of the cardiac muscle; the constitutional disease which has caused it, or with which it is associated; the condition of the vessels; the patient's age, sex, status in life, habits, occupations, and hereditary traits; the degree to which the disorder is amenable to treatment, and the skill or lack of it in its management. We must realize at the outset, as I have intimated, that if recovery takes place it may be complete or only partial. Entire recovery is possible in functional diseases, while only partial recovery can be looked for in organic. But even if an absolute physical cure is impossible, it may be relative. The functions of a heart may be temporarily restored, often for a long time, and this is of very great importance to the individual.

The matter of most concern, however, both to the individual and to society, is a forecast of the probable duration of life under given conditions, and the extent of the field in which one's energies may be applied to the best advantage, coupled with the least danger. Naturally, this matter has always been one of absorbing interest. As every new phase of a disease has become apparent, it has been studied with reference to the final issue, so that we are gradually increasing our knowledge in this direction. The subject has been looked at from many points of view; in the light of etiology, from the clinical side, from post-mortem revelations, and from experimentation on animals. This last method is a field that has yielded little as yet, but is likely to bear much fruit in the near future. The most valuable information available at the present time has been derived from clinical observations confirmed by post-mortem evidence. Unfortunately, many of the observations that have been utilized have been based on clinical signs alone, and are, therefore, of little value. If, however, we study the returns derived from trustworthy sources, based on both clinical histories and autopsical revelations, we have data that are correct as far as they go, and which to that extent are adapted for approximate prognoses. For the reasons above given, prognoses based on percentages can never be mathematically correct. Let us now take up the subject in detail.

In infants under one year the outlook is particularly unfavorable in any form of heart disease. During childhood it is worse than in adult life; children with serious valvular diseases before the age of eight seldom reach puberty, for as they approach that period heart weakness is apt to set in. Holt found that in 225 cases of congenital heart disease 60 per cent. of the patients died before the end of the fifth year, and one-half during the first two months; 16 per cent., however, lived more than sixteen years, and 8 per cent. over thirty years. Serious valvular lesions progress more quickly in children than in adults; owing to their rapid growth, and the corresponding demands made upon their strength, cardiac dilatation occurs early. Acute diseases still further increase the danger.[1]

But it is not immediate. In fact, acute and chronic endocarditis in children are rarely of themselves fatal, death being usually due to associated conditions, particularly pneumonia and pleurisy. In mild forms of acute endorcarditis occurring in children, recovery may be looked for, though recurrences are to be anticipated. First attacks are apt to be overlooked. Rheumatism and the acute infective diseases are the chief sources of danger in the heart diseases of small children. Where cardiac disease develops after puberty, life will usually be prolonged into the fourth decade. After the age of forty, the prognosis in all valvular diseases is affected unfavorably by the tendency to myocardial and arterial degeneration, and the danger of losing compensation that has been developed. In old age, compensation in valvular disease, if once lost, is very rarely regained.[2] Removal of tonsils and adenoids, however, may be helpful in

preventing recurrences. In general, these and decay in teeth are now thought to be sources of infection. If there is doubt as to the presence of an alveolar abscess, an *x*-ray should be taken.

Women, who as a rule, lead a less active and more regular life than men, are considered to have a better expectation of life, aside from the special risk they run during pregnancy and parturition. During pregnancy the greatest danger is from the increased pressure of the abdominal organs, though this is greater in a forward than in an upward direction. The severe expulsive efforts that must be made in parturition are a considerable strain upon the heart. However, the treatment of heart complications in pregnant women is much better understood than formerly, and, while uncompensated endocarditis means danger to both mother and child, a valvular affection with good compensation need not cause any serious apprehension, as the actual danger to life is not very great. The most unfavorable lesion is mitral stenosis. If death does not occur, abortion or placental apoplexy may result. Where valvular disease is present, it may be necessary to induce artificial labor. The safest anesthetics for use in these cases are nitrous oxide and ether. Strychnine is sometimes given to pregnant women and after childbirth, but digitalis is rarely called for.

With regard to men, the prognosis is most unfavorable where the occupation pursued calls for continuous or severe physical strain, or exposure to inclement weather, especially if the patient is addicted to the use of stimulants. Among either men or women, a sudden tax on the system, such as fright or great emotion, overeating or drinking, arrested digestion, or the overuse of tobacco may hasten the fatal issue. Indigestion, or the eating of an immoderate amount of food, is a not uncommon cause of sudden death in the aged.

The outlook is more favorable in mitral insufficiency than in any other form of valvular disease; this affection, when uncomplicated, is not incompatible with a long life. There is a relative form which is common in convalescence, among neurotic individuals, and after severe physical exercise, which usually disappears when the special strain is past. In some patients it may be a permanency, as in laboring men engaged in work involving continuous severe strain. When simple mitral insufficiency is acquired in early life, compensatory hypertrophy seems to occur more readily than in any other form of valvular disease. It is, therefore, to be considered comparatively harmless. There is danger, however, that in practice it may be confused with mitral stenosis, a far more dangerous lesion. My hospital records show that this error is not infrequently made. In a record of 102 fatal cases of heart disease, there is not a single case of death from uncomplicated mitral insufficiency, and I am not sure that it ever causes death of itself, but the organic variety is very likely to be complicated with other valvular lesions. According to my figures, such complication occurs in 86 per cent. of the cases.

As already said, mitral obstruction has a graver outlook than mitral insufficiency. Where it is present, mitral disease is evidently well established. Another danger in these cases is from embolism, which may occur, according to my experience, in 20 per cent. The average age at which death takes place, as given by various authorities, is between 30 and 40 years. In Broadbent's 53 cases of mitral stenosis, it was 33 years for males and 37.38 for females. Hayden's[3] 15 cases averaged 29.26 years. In Fagge's 42 fatal cases, the average was 37.83 years. Other valves were affected, however, in a third of these cases. Samways'[4] found that in 196 cases taken from the Guy's Hospital records the average age at death among patients of both sexes, was 38 1 3 years, the average in severe stenosis being 33.6 and in the milder forms 43.6. In Dyce Duckworth's cases, 264 in all, but not all supported by post-mortem findings, the average age was 35. Sansom found it 32.7. According to my own statistics, in one series numbering 19 cases the average age was 39.2, but death most frequently took place between 37 and 38, while the extremes varied from 23 to 70. In one series of collected cases, 100 in number, I found the average age to be 35, and in another series 33. In another series of 57, ranging from 13 to 67, nearly half died between 30 and 40. Based on post-mortem evidence, therefore, the expectation of death is in the fourth decade, and, according to what we know at present, at about the age of 34. I had under observation some years ago, however, a patient of 73, with the typical signs of mitral stenosis, including the purring thrill. This case, as well as another of which I have a record, was probably congenital. Sudden death is as rare, comparatively, in mitral stenosis as it is frequent in aortic insufficiency. In five of my cases it was said that the disease had lasted from three to thirty years.

The danger in aortic insufficiency depends somewhat upon whether or not arteriosclerosis or angina is present, and whether there is much displacement, or much alteration in the contour of the heart. It has been questioned whether this affection is as much graver than aortic stenosis as has been supposed. The average age at death, in 50 of my cases, was 40, as against 41.7 in aortic stenosis, but only a few of the stenosis cases were uncomplicated by other valvular disorders. Indeed, but few cases of pure aortic stenosis have been recorded. When it does occur, however, it has a comparatively favorable outlook. In my record of 8 cases, the average age at death was 56, while two patients lived to the age of 70 and one to 90. I agree with Fagge, that where aortic stenosis and insufficiency are combined, it is the insufficiency that governs the prognosis. Of Hayden's 26 aortic cases, one-half were combined with insufficiency. I make it 65 per cent. in my cases. According to my figures, a complicated case of aortic obstruction is almost as grave as one of incompetence, while an uncomplicated case is much less so. Arteriosclerosis is always an unfavorable symptom in aortic obstruction. It is, however, the grade of obstruction which governs the prognosis; if it is but slight, the outlook is comparatively good. The average age at death in Broadbent's cases was 40 years, his oldest case being 53. I agree with him that on the whole aortic stenosis is less serious than aortic insufficiency or mitral stenosis, but it has been my experience that sudden death is as common in aortic stenosis as in insufficiency. According to my records, it is 20 per cent. in both affections. Hayden found it 18 per cent., in both forms of aortic disease.

With regard to pulmonary valve disease, it may be said that the prognosis is always grave in congenital insufficiency, and in congenital obstruction (stenosis) most patients die before the fourth year, generally of tuberculosis, though cases have been

known where death did not occur until the age of 40. Acquired disease of either type is less serious as to outlook; I have known of a case of acquired insufficiency where the patient lived to the age of 70, and a patient of Schwalbe's with acquired obstruction lived to be 84. In 15 cases which I collected the average age at death was 42.8, while of 4 cases of my own one lived to be 56. These cases are not, however, sufficiently numerous to be of much value for statistical purposes. Pulmonary obstruction is the point about which all congenital cardiac anomalies are apt to center, and as a rule they are not compatible with a long life. The pulmonary valve is also in a situation which renders it liable to be compressed by external influences, such as adhesions.

Tricuspid affections are rarely congenital. The congenital form of tricuspid obstruction is, however, the most dangerous of all valvular diseases, and patients seldom survive more than a short time. It usually occurs late in the course of general valvular disease, the tricuspid being the latest valve to be affected. The majority of patients die before 40, but occasionally one lives to old age; in one case that I have reported, the age at death was 70, and a patient of Leudet's reached 64. Those in easy circumstances of life may be expected to live longer than those engaged in hard labor or in unfavorable surroundings, and the disease seems to be more dangerous in women than in men. It appears to be less rare than has been supposed; in 196 cases of valvular disease, Samways found 32 of tricuspid stenosis. Tricuspid insufficiency may be a temporary affair, and of small importance, but if it persists the prognosis is bad. It is apt to be a terminal affection, secondary to some other valvular disease or disease of the lungs, and here the outlook is not a favorable one.

The comparative gravity of the various valvular affections is given differently by different authorities. If we are to judge by the average age at death, the figures given above would put the order as follows: (1) Mitral obstruction (stenosis), (2) aortic insufficiency, (3) aortic obstruction (stenosis), (4) mitral insufficiency.

Broadbent has given this order of gravity for childhood and early adolescence, but my statistics are taken almost altogether from adult cases. The order for cases in general, as given by Broadbent and Leyden, is as follows: (1) Aortic incompetence, (2) mitral stenosis, (3) aortic stenosis, (4) mitral regurgitation.

The order given by Wilks, Peacock, Bristowe, Fagge, and Pye-Smith is as follows: (1) Aortic regurgitation, (2) mitral regurgitation, (3) mitral stenosis, (4) aortic obstruction.

Green[5] gives the following order: (1) Aortic regurgitation, (2) mitral stenosis, (3) aortic stenosis, (4) mitral regurgitation.

Walshe has given the order as follows: (1) Tricuspid regurgitation, (2) mitral regurgitation, (3) mitral stenosis, (4) aortic incompetence, (5) pulmonary obstruction, (6) aortic obstruction.

With regard to myocardial diseases, degenerations resulting from the continued fevers, such as typhoid and diphtheria, are apt to disappear after convalescene. Under intelligent treatment, the fat heart of corpulence may be greatly improved. But myocardial disease is a more frequent cause of death than is generally supposed. In cases with arteriosclerosis or degeneration of the heart walls, a persistently weak pulse, especially if there is a difference in the radials, means that danger is never far off. In cases of fatty heart, death sometimes occurs as if from a stroke of apoplexy. The immediate cause of death may be thrombi detached from the chambers of the heart, acute dilatation, or even rupture; or a gastrointestinal disorders, or pneumonia may put a strain upon the heart that is beyond its power of resistance. In many cases the terminal affection is some disease of lungs, liver, or kidneys. Myocardial syphilis is sometimes a cause of death.

In malignant diseases of the heart, either new growths or infective endocarditis or carditis, a fatal result is pretty generally to be expected.

Functional diseases of the heart are not in themselves dangerous to life, but it cannot be denied that they render the organ more liable to disease of a more serious type.

But we must remember with regard to statistics that though they may apply to cases taken in the mass, they may not be true of specific instances When taken from hospital records, they are correct as to figures, and therefore are a proper basis for comparison, but they do not tell of the average duration of the disease, or of many other attendant circumstances. If we require figures, we will have to be content with our present tables until statistics are more complete. That is, if we are willing to rely on this kind of evidence. Any other kind, apart from the post-mortem in conjunction with the clinical history, involves a large amount of the personal equation, and leaves abundant room for theorizing, according to the bent of the individual mind. But such theories should not be accepted unless supported by animal experimentation, of which little has been done as yet.

With regard to the bearing of cardiac murmurs on prognosis, the intensity of the murmur is not a measure of the gravity or extent of the disease process present. Unfavorable signs are well-defined murmurs that come and go, causing one to suspect the presence of loose vegetations, and musical murmurs attended by fever, which indicate the probability of an ulcerated or ruptured valve. Where a loud murmur is present, there is probably a large opening, and when a loud murmur changes to a soft one the power of the heart is likely to be beginning to fail. Systolic murmurs are of less grave significance than diastolic. Cheyne-Stokes breathing, or the Adams-Stoke syndrome, point to probable cerebral implication; in rare cases they may disappear, but they are always a warning of danger from cerebral disease.

The prognosis in valvular disease depends on the question of efficient or non-efficient compensation much more than upon auscultatory signs, provided the apex beat is in approximately a normal position, rhythm regular, the action of the heart good, and the transverse dulness not materially increased. Of course, in any form of endocarditis, recurring attacks of inflammatory rheumatism are very unfavorable, and a sharp attack of pneumonia, or any long illness that causes a severe drain on the vital forces, may result in failure of the heart. But as long as compensation is well maintained there is no immediate cause to apprehend sudden death, except from embolism. This is always a possibility to be kept in mind. Still, the separation of an embolus need not always have a fatal result; the embolus may not lodge in a location where it will do serious damage. Although it will probably cause immediate death if it lodges

in the medulla or pons—and I have personally known this result to follow the lodging of a clot in the latter location—if it only reaches a "silent center" it may do little harm. Lodged in the lungs or liver, little danger need be apprehended from it. Diseases of the right side of the heart are most to be feared, as the venous congestion is greater than in affections of the left heart, and there is, therefore, a more profuse exudation, with its attendant consequences. Congestion of the kidneys is commonly held to be the cause of the dropsical effusions so often present in the terminal stages of heart affections, but the liver and spleen are nearly as frequently implicated.

No matter what the nature, location, and extent of a valvular disease, the prognosis does not depend so much on the valve affection itself as on the condition of the myocardium. This we can now determine by the various tests for cardiac efficiency. According to J. S. Langford[6] the supreme test is by exercise and blood pressure. If there is serious disease, after the patient has climbed two flights of stairs he will come back breathless, in more or less distress, with great irregularity of the heart, and a murmur may be revealed. If the systolic pressure is then taken, it will be found to have fallen, while the diastolic has remained stationary.

Complications must be taken into account. Pericardial attachment unfavorably affects the prognosis because it interferes with the contraction of the chambers, and promotes dilatation. Associated diseases of the lungs, liver, or gastrointestinal tract affect the prognosis unfavorably, as they tend to cause congestion of these organs and the passive engorgement of internal viscera already existing, and interfere with normal metabolism. Chronic indigestion from any cause adds to the gravity of cardiac disease by permitting the development of gas in the stomach or intestines, producing pressure against the laboring heart. Sclerosis of vessels is also unfavorable, as the altered caliber of the arteries, and to some extent of the veins, interferes with the passage of the blood current, thus putting a further burden upon the heart. Any acute disease of internal organs, and especially pneumonia, increases the danger. Many chronic diseases, and more especially gout, rheumatism, and syphilis, which are among the prominent causes of cardiac disease, may add fuel to the flames at any time that an acute exacerbation occurs.

Among the most important considerations are the station in life occupied by the patient, his temperament, his occupation, and his environment. It is fortunate when a cardiac patient has an equable disposition, for it will surely be tried as his disease progresses. His cardiac compensation in valvular diseases or efficiency in myocardial will be better maintained if he will steel himself against worries and all kinds of emotional excitement. And this is one of the difficulties in most cases, disquieting to both patient and physician. The continuous dosing that becomes necessary as the disease advances, and the strict rules laid down as to dietary and mode of life, are annoying to the patient, and he appeals to his physician for personal liberty, even if at the risk of his life. With regard to occupation, an important point to be considered is whether it entails severe physical strain. Persons who develop cardiac insufficiency from time to time are especially liable to attacks of heart failure, and it may be extremely difficult, if not impossible, in instances where the wife or family is dependent on the patient for support, to find him an occupation that will be sufficiently remunerative without causing too great a strain on his heart. The older one gets, the greater the danger. And the difficulty will be increased if there is a history of cardiac disability in his family. There can be no doubt that there is a hereditary tendency in cardiac disease just as there is in cerebral hemorrhage. And if in addition to unsatisfactory surroundings and the pinch of poverty the unfortunate patient has been at any time overindulgent in food or drink, persists in smoking, and drinks strong coffee when it causes cardiac irregularity, or gives rein to loose habits, the outlook will be correspondingly worse.

There is no doubt that heart cases are benefited by a suitable climate and a not too great elevation. It is thought by some that a moderate elevation above the sea level, at no great distance from the sea, is desirable. As a rule, elevations exceeding 1,500 feet should be avoided by patients suffering from chronic cardiac insufficiency.

The method of treatment has an important bearing on the prognosis. Lack of proper rest in the acute cardiac diseases of children and overdosing with drugs of the digitalis group are responsible for deaths which might have been avoided by wider knowledge or experience. The proper indications for the use of any drug of the digitalis group especially are often improperly understood, and various forms of these drugs are used without a knowledge of their therapeutic values and their limitations.

Blood pressure has much to do with the prognosis. A high blood pressure is a bad sign, even in the absence of interstitial nephritis. When the high pressure can be relieved by an appropriate dietary, laxatives, and suitable medication, the danger to life is lessened, but even if the pressure has been reduced to the standard for the individual, it is still not a guarantee against arterial hemorrhage, though the expectation of life is, of course, improved. In all persons subject to high pressure, there is especial danger of cerebral hemorrhage or heart failure; for, even if the coronary arteries are not involved, increased pressure indicates that the heart is doing more than its normal quantum of work.

So far as interstitial nephritis is concerned, it need not necessarily be a bugbear. If metabolism can be regulated, and the flow of urine maintained at a reasonable standard, so that there is no edema, there will be no immediate danger to life. Edema that cannot be controlled, however, is a sign of the rapidly approaching end.

The dietary of heart patients should be carefully regulated. There should be no physical or mental strain, no overeating or overdrinking, and the habits of life should be orderly. But this does not mean abstinence from any kind of work; idleness may lead to the formation of habits that will do more harm than the previous occupation, and a certain amount of activity and even of responsibility will be helpful. Angina is often a good test of the way one's life is to be ordered. Any exertion, mental or physical, or any habit such as the overuse of tobacco or coffee, or anything in the dietary that causes gastrointestinal gas so as to produce angina, should be suspended. The least sign of such attacks should be a warning.

The most important sign of the approaching end

is cardiac weakness that cannot be controlled by ordinary dosage with the group of remedies of which digitalis is the chief. When a patient's irregularities for years have been controlled by these remedies their failure to be effective shows that the end is near. Ascites is always an unfavorable sign; it points to liver disease. When the kidneys begin to be inefficient, treatment may at first be successful, but it will only put off the fatal issue temporarily. And this is the usual manner of death. With the cardiac failure there is necessarily congestion of such internal organs as the lungs, liver, and the organs of the splanchnic area, and death may be due to them secondarily instead of to the condition of the heart itself. If cyanosis fails to yield to appropriate treatment, it shows a very serious condition and the end may be expected shortly. This is also the case where dyspnea is present while the patient is at rest and is unimproved by proper treatment.

If acute aortitis is caused by syphilis, and at least half of the cases that come to our attention are of such origin, the outlook depends upon the use of anti-luetic treatment. If caused by tuberculosis, the prognosis will depend largely on the successful management of the primary disease. Where it is the result of violent physical exertion if this is continued an aneurysm may develop. But this is mere theorizing; for, as far as I have been able to learn, such a condition has never been recognized during life. However, there is a probability that the acute form may, as already said, end in recovery; but it is more likely to take on the chronic form. Associated with malignant endocarditis in purulent deposits, a fatal termination is to be expected.

In the chronic forms of aortitis the expectation of life will depend largely on whether the primary disease, whatever it may be, is amenable to treatment, and whether the patient can avoid any intoxication like lead, alcohol, tobacco, or has been overworked. The chronic aortitis of senility is incurable. In Hodgson's disease, or dilatation of the thoracic aorta there is no immediate danger to life. Simple dilatations of the aorta are not uncommon among men who use violent muscular efforts and may be either permanent or temporary.

The larger aneurysms have not thus far been successfully treated by surgeons. Medical treatment insures a longer lease of life, but the earlier the diagnosis can be made the better the prognosis. Small aneurysms such as occur in cerebral hemorrhage, are common. If there is an extensive rupture with a large clot near the great nerve centers, the end is near. But there are various degrees of rupture. It is seldom that the first apoplectic stroke is fatal. But they are likely to recur in from one to five years. Few survive the third attack. Complete recovery is very rare.

In cardiovascular thrombosis the expectation of life depends largely on the age of the individual, the location of the clot, its benign or malignant character, and whether or not it is associated with embolism. If the pons is affected death may be immediate; if the cerebrum the danger will be less. If at its base the prognosis will be more unfavorable than in its upper portions. But thrombosis has always a better outlook than cerebral hemorrhage; the symptoms may pass away in a few hours or a few days. Heart clots are usually found in the agonal hours immediately preceding death. In thrombosis of the auricles the fatal termination may be deferred as in a case described by Dock. In ordinary thrombosis the prognosis depends largely on whether the thrombus is benign or malignant; in the former case there is a good chance for recovery provided the clot does not seriously interfere with the nerve centers or with the course of the blood current in the more important parts of the body. In the reported cases of venous thrombosis associated with cardiac disease the mortality is about 75 per cent.

The condition of the arterial system must always be taken into account in making a prognosis. Where there are hard arteries, not only is the heart compelled to use more energy in driving the blood through stiffened channels but there is also interference with normal metabolism.

In compensatory hypertrophies the right ventricle fails, as a rule, earlier than the left. Hypertrophy compensates for a variable period, dependent chiefly on the extent of the disease in the valve or valves affected. It was at one time computed that the expectation of life in ordinary cases is from two to four years after compensation has failed. The expectation of life in cardiac diseases has been greatly improved, however, by a closer attention to diagnosis, a more discriminating use of drugs, and a recognition of the successes obtained by mechanical methods. Whether or not the claim of advocates of the Nauheim system that this form of treatment adds an average of ten years to life is well founded is an interesting question.

It is plain that the physician cannot be too careful in framing a prognosis. As has been shown the expectation of life in any particular case of cardiac disease is uncertain, as the governing factors may be unknown or uncontrollable. Patients may recover again and again from alarming attacks of heart failure, while on the other hand, when the cardiac disease is progressing favorably some intercurrent affection may precipitate the fatal issue. The patient may feel like crying with the Psalmist, "Lord, make me to know mine end and the measure of my days, what it is," for only He knows. Mortals can only surmise. In cardiovascular diseases, therefore, the prognosis should always be guarded.

CLINICAL PSYCHOLOGY IN ITS RELATION TO THE SCHOOL AND TO SOCIAL MEDICINE.

A SUGGESTION FOR AN ACTIVE AFFILIATION.

By J. VICTOR HABERMAN, A.B., M.D., D.M. (BERLIN), NEW YORK.

INSTRUCTOR IN PSYCHOTHERAPY AND CLINICAL PSYCHOLOGY, COLLEGE OF PHYSICIANS AND SURGEONS, COLUMBIA UNIVERSITY; ATTENDING PHYSICIAN, PSYCHOTHERAPY ROOM, DEPARTMENT OF NEUROLOGY, VANDERBILT CLINIC.

"Wer die Jugend hat, der hat die Zukunft."

Let me endeavor to point out briefly and tersely the problems in clinical psychology which belong both to the school and the clinic, and bring up questions to be solved in part by both, questions which, in themselves, suggest measures for an

urgent campaign into the all-important and far-reaching fields of prophylaxis, remedial pedagogics, and preventive medicine.

In the first place, there is the daily problem of the child whose behavior and progress is not just entirely normal. It does not keep pace with the others in its class, or falls behind, or does not progress; or again, cannot get along with the other children, or is just "queer," "odd," or "precocious"; or again, is considered "difficult," one that cannot be managed in the usual way; or the child plays truant, or it is an over-sensitive or over-emotional child, or morbidly introspective, or nervous and fearful. Or again, it may be chronically fatigued or twitchy and restless, etc., etc. Such children have but one foot beyond the threshold of normality, and need not yet be rubricked under the abnormal. Just what may the matter be, and what the cause of it (and often momentous too, the course of it)? It is for the clinical psychologist (who is physician and neurologist as well as psychologist) to determine; and it is for him, likewise, in connection with the pedagogue, to suggest the remedy.

From this stage of the *abnormal normal* child there are all grades into the really abnormal—into neuropathy, psychopathy, and mental defectiveness. The school spots and labels some of these, the outspoken ones. But neither teachers (nor phychologists!) should attempt diagnoses, and it is left for the psychoclinicist to learn whether the root of the trouble is physical, physiological, environmental, pedagogical, or psychological; and, if the latter, to sift the mental processes and discover if there is just functional disharmony or psychopathy, or if the intelligence, as such, is involved.

This latter—this problem of the intelligence examination—is most intricate and difficult, and Binet-testing—which has become a kind of schoolgirl hysteria with us, and the method par excellence of deciding both diagnosis and fate of the abnormals at most of our clinics—does not solve it in the least. In fact, the Binet-Simon tests are of no value whatsoever in estimating mentally the individual slightly abnormal or really abnormal child, in estimating it for diagnostic, prophylactic, prognostic, sanative, or corrective purposes. The important fact is to probe the component parts of intelligence (memory, comprehension, combination, attention, etc.), and considerable outside the sphere of intelligence beside, and learn if there is any pedagogical retardation, "backwardness," "deficiency," or "defect," and whether in all faculties, or only in certain ones, whether the abnormalities lie in the thought tendencies (or tempo), or, finally, in the general or just some special arc of psychotechnic play. Only in this way can the separate intellectual factors and the separate mental abnormalities be sifted and scrutinized for determinants of diagnosis and remedial procedure.

Out of such studies, in Germany, sprang an interesting pedagogical departure. Schulrat Sickinger of Mannheim, namely, thought it to the advantage of that group of children among the normals who were slower in their advance than the majority of their class, and who in consequence were often left back and suffered through the fear of doing poor work, and through having to sit overlong at their home-exercises, through scolding and reproaches, etc., that they be taken care of and developed in *special classes* (Förder-Klassen), whose work and advance was in keeping with their (somewhat subnormal) ability. And such classes were then instituted.

Further study and examination brought out the fact that some students instead of being retarded were advanced along certain lines, that is, had certain faculties abnormally developed. Do they not also suffer in being held back, because of the general class neveau, when in these certain faculties they could, if given the chance, forge ahead? Hence came the idea (suggested by Petzold) to have extra schools not only for the retarded but also for advanced students; and this has crystallized into an actual, practical procedure in the Charlottenburg- (Berlin) Volks-Schule, in which there has been added to every normal class, a subclass (termed "B-Klasse"), and parallel with it an advanced or talent-class (termed "A-Klasse").

In the above arrangement, however, a flaw might be detected inasmuch as I have said that the facultative intelligence examination may show not all the faculties defective, not all advanced, but, namely, that some may be just normal, some below and some above normality. An individual, for instance, may have an exceptional memory and yet very poor combinational ability; or combinational ability in words and speech may be deplorably bad while that for line and color may be of singular excellence (often enough seen in artists). Hence a child ought to be sent to a superclass for certain subjects and to a subclass, possibly, for another, remaining in the normal class for still other subjects. A class procedure with this idea as its underlying principle has indeed been suggested at the Dresden Pedagogical Congress in 1911 (Raschke of Vienna being the first to propose it), but whether put into practical effect as yet I do not know.

At every turn in this pedagogical advance, the need of the clinical psychologist comes up, for not only must the status of the various intellectual faculties be determined, but the causes or reasons for retardation or defectiveness in the various faculties, if present, be elicited (diagnosed) by him, again whether physical, physiological, or psychological, whether environmental or pedagogic, and then, too, the prognosis given, whether easily remedied (and how) or whether only with great difficulty, or, in fact, not at all. A child with nasal or ethmoid disease, for instance, may give a mental picture of intellectual debility or mild imbecility ("aprosexia nasalis"), although it is mentally normal. Congenital syphilis may produce all types of mental disturbances and defect, from mere inability to concentrate, to absolute idiocy.[2] And this latter is remediable, even curable. Various functional mental disturbances in the so-called psychopathic constitution, as well as in the neurasthenic, hysterical, obsessive, etc., may also have the strongest deleterious effect upon the intellectual faculties, and these children, if treated and properly trained, improve or again become normal. Abnormalities in the internal secretions (mono- or polyglandular irregularities) may cause mild or serious retardation, possibly mental infantilism, even precocious advance (hyperpinealism?). In fact, such important strides have been made of late in this field of science, that no one, at this stage of investigation, can aver or deny that the internal secretions are not the constructing, stimulating, and inhibiting factors in the entire upbuild and psychodynamic leverage of the brain and mind. Our therapeutic and experimentally therapeutic ad-

ministration of these gland secretions, so easily carried out, may in time prove of inestimable value in the treatment of mental defects and abnormalities, possibly, too, in the mitigation of fatigue and pathologically affected attention, in the goading of interest, diligence, ambition, even in the stimulation of mental exuberance, physical growth, and general maturity. Very aptly did Woods Hutchinson express himself not long ago when he said, "We are such stuff as ductless glands are made of, and our little life is rounded with a sheep."

But though psychopathic and neuropathic children may easily enough be recognized by the physician, the problem itself of the intelligence examination, the actual probing to ascertain if intellectual defect is present, or if a child is subnormal or supernormal, is very difficult indeed and only just out of its swaddling clothes. To advance in this work much cooperation between the school, which provides the facilities of observing normal and slightly abnormal children, and the clinic with its outspokenly abnormal charges (the abnormalities in pure and concentrated cultures, so to speak) must still be necessary.

There is another decidedly grave problem, the one of most far-reaching significance, to be taken up by the school, in cooperation with the clinical psychologist. Can one, during the school years, discern signs or symptoms in the child which possibly presage nervous or mental trouble or disaster for it in the near or remoter future? And if this is so, could one not institute proceedings which would keep such child from becoming a future neurasthenic or hysterical or obsessed or psychopathic individual, or, indeed, from becoming a delinquent or criminal, or from the fate of insanity itself? And can aught be done for that pathetic class of mortals who are entirely normal up to the eleventh or twelfth year, or to puberty, and then suddenly cease progressing, or begin to deteriorate into one of the deplorable forms of dementia? What an immense proportion of our members are finally disposed of under one or another of these ominous headings!

And yet we know through such studies as those of Ziehen, Stelzner, and others, that a very large number of such individuals show prognostic signs of impending mischief in childhood (or may have a sinister augury even in their heredity) and that ever so many can be saved to themselves and the State if treated and mentally nurtured in time.

Why are society and Medicine asleep to this vastly important problem? With the abundance of talk on preventive medicine, of insanity exhibits, public propagandas and congresses on the part of psychiatrists and eugenic enthusiasts, it is amazing that the matter is not more opportunely taken up at the door of clinical psychology and the schools, here where it can be easily and simply inaugurated, and on a tremendous scale, here in the school years of the child—at that period in the life of these future unfortunates when they could still possibly be succored! It is evident that the gravity of it is not realized by the physician (and it is primarily a matter for the physician, not for the educationalist) or he is too busy with other problems to give much support to this one. It is possible, too, that just as the subject of psychotherapy was first taken note of after Christian Science and other modern healing cults assumed formidable proportions, so clinical psychology will first be legitimatized within the field of medicine after the schools of education and the psychologist have fostered it and made the province their own.

In the school this problem could be practically pursued in the following way: We know of a large series of signs and symptoms, often slight, often outspoken, as occurring in the childhood of such adult patients whom we treat for hysteria, neuro- or psychopathy, and certain psychoses, as well as in the so-called psychopathic constitutions of various types, the simple abnormals, the affect-individuals, the déséquilibrés, and such who evidence ethical and moral defects, and whom we find among the delinquents and many criminals. We must look for such signs and symptoms in all school children, and, when found, subject such child to careful scrutiny. A talk could be given to the mothers or guardians and the teachers concerning these signs and symptoms,* and then a sheet upon which the various facts are printed could be given them to fill out in respect to their own child or children. At our clinic we employ such a "questionaire," our *psychopathy-sheet*, as it is called, and it has served an excellent purpose, both in spotting the child in danger of some future trouble, and as an aid in the diagonsis of adult patients. Sleep-walking, for instance, points to hysteria in an extremely large number of cases. Bed-wetting, on the other hand, may be nothing but a bad habit, yet it may also be a sign of epilepsy, or, again, a mark of neuropathy or psychopathy in a child. Mistakes in writing may not only be due to poor scholarship; they may be due to nerve-fatigue or they may even be a premonitory forerunner in the epileptic, this latter condition having been pointed out by Stadelmann in his study of the school-child,' etc., etc. In an adult who comes because of an unexplainable pain or symptom, the history of his having been a sleepwalker in childhood, or of having had "stiff-attacks" or periods in which he couldn't see, or walk, or talk, etc., would lead us to conclude that he had undoubtedly had hysteria, and that the present symptom, if no cause can be found for it, was very probably hysterical.

These sheets could then be looked over in the school, and such children as showed any abnormalities be referred to the clinical psychologist for further interrogation and examination. A diagnosis made, the physician could then confer with the pedagog, and medical measures, or remedial pedagogics, or both, be advised and instituted in the way of treatment.

Vanderbilt Clinic,

Department of Neurology.

PSYCHOPATHY SHEET.†

(T. D., neurotic, hysterical, psychasthenic, psychopathic, psychotic.)

Underline any of the following symptoms or conditions, if present. State duration.

1. Bedwetting.
2. Walking, talking, or screaming in sleep. Night terrors.
3. Fits of temper, rage, or inability to control feelings. Destructiveness.
4. Attacks of convulsions, stiffness, spasms, faints, vertigo, shaking, "absences," "queer spells."
5. Spells of vomiting, migraine, car-sickness, difficult breathing.
6. Hysterical, agitated, depressed conditions; apathy.

*This could even be given by the principals of the schools, the matter for instruction being prepared by the psycho-clinicist.

†Copies of this sheet may be obtained from the Fetzer Press, 62 Reade Street, City.

7. Sudden, extreme changes of mood, or an entire change in disposition.
8. Being over-timid or fearful, over-bashful, over-scrupulous.
9. Tendency to morbid fears, obsessions, impulsions.
10. Being abnormally cruel, or tender; over-susceptible, over-emotional, over-sensitive, over-irritable.
11. Temporary loss of voice, or power of arms, or of legs, or sensation (of any part).
12. Loss of memory (general, or for certain periods); abnormal lack of attention.
13. Loss of vision (for periods); seeing double.
14. Headaches, sleeplessness, chronic fatigue.
15. Telling lies, playing truant, running away, stealing.
16. Easily led or misled; difficult to train or bring up.
17. Inability to stick to anything (play or work); shiftlessness.
18. Abnormal behavior or acts.
19. Strange fantasies (especially toward or at night), hallucinations, illusions.
20. Abnormal or imperative or fixed ideas; paranoid ideas.
21. Sexual precocity; sexual abnormalities.

Note (underline) if any of the following abnormalities are present:

a. Asymmetry of face, skull, nerve innervation.
b. Abnormality (atypical or misformed) of head, ears, teeth, palate, hands, toes, genitals.
c. Double hair-spiral, growing together of eyebrows, irregular growth of hair into forehead, etc.
d. Irregularity of pupils, difference in color of both irides, pigment or other abnormalities.
e. Left-handedness; speech defect.
f. Infantilism (of stature, general development, etc.)

Knowledge of the heredity of the child is often of greatest importance, especially in the case of those children referred to who progress normally until puberty, and then degenerate. A talk on heredity could, therefore, also be given to the parents (or a heredity "questionaire" or a small brochure be prepared and distributed among them), and it could be pointed out that ever so much can be done for a child to thwart the bad effects of heredity if the facts are known in time, and that, on the other hand, if no counter effort is instituted there is a likely chance of the abnormalities of the ascendants again appearing in the descendants, or if not the same abnormalities, other abnormalities. Thus, many parents could be induced to confide data of this nature to the psychoclinicist in charge.

Finally, other problems, some entirely pedagogical, could probably later be furthered by pedagog and psychoclinicist working conjointly, the problem of fatigue, or of artificially stimulated interest and emotion in instruction—for our studies in psychopathy teach us that happenings associated with affect or emotion are remembered almost permanently—then, the problem of longer or shorter sessions for each subject, whether brief periods of relaxation after recitations aid memory (suggested by the psychologist Gaupp), whether methods of concentration and suggestion similar to that used in hypnotherapy could at times be employed—a certain modulation of voice, a certain subdued light in the room, etc., especially in the giving of ethical instructions, etc., etc.

The various teachers in the school ought to be taught something about these faculties of intelligence and their examination, as well as something about normal and abnormal variations from the rule of behavior and thinking. Some one person in the school, let us say a social worker, ought to familiarize herself with the various factors in clinical psychology and be in constant touch with all the classes, and so with those children singled out for observation (and supervise in the singling out of such children), who also would be there to get the data together for the clinical psychologist when he called, or would bring this to him, together with the children to be examined. In other words, just as there is a visiting school physician, and his assistant, the school-nurse, so the school should have its visiting clinical-psychologist, and, to aid him, an assistant psychologist, or social worker at the school.

At most it would be but a beginning, as only a few paths have as yet been blazed. But this work is rich of promise, and when fully and carefully carried out will prove an indispensable aid to the school in grading and classifying its charges, and of the greatest boon to the growing child in spying out its abnormalities at the earliest possible moment and endeavoring to obviate them, thus saving the adult from aberration, chronic illness, or infirmity, and society ever so many of its variously invalided mortals.

60 WEST EIGHTY-FIFTH STREET.

THE SIGNIFICANCE OF THE PRESENCE OF ACID-FAST BACILLI IN THE FECES OF THE PATIENTS SUFFERING FROM JOINT DISEASE.*

BY HENRY KELLER, M.D.,
NEW YORK.
INSTRUCTOR IN ORTHOPEDIC SURGERY, N. Y. POLYCLINIC MEDICAL SCHOOL AND HOSPITAL,
AND
A. J. MORAVEK, M.D.,
NEW YORK.
DIRECTOR NEW YORK DIAGNOSTIC LABORATORY.

IT is our belief as a result of our experimental and clinical investigation lasting over a year (1) that the acid-fast bacillus found in the feces resisting the decolorization with 25 per cent. nitric acid, watery solution, followed by alcohol (80 per cent.), is a tubercle bacillus and nothing else; (2) that the same acid-fast bacillus is viable, able to grow on culture media, and (3) that when those cultures are injected into guinea pigs they produce tuberculosis.

Experimental Proof.—On June 24, 1914, eight healthy guinea pigs were placed in aseptic compartments for one hour daily in order that we might gather their feces and look for the presence of acid-fast bacilli. All of the specimens were negative. On the fourth day all of the animals were injected with a suspension of tubercle bacilli. Three received their injection into the hip joints, three into the knees, and two subcutaneously. Twenty-four hours after the injections, and every

*Read before the Medical Association of the Greater City of New York, May 17, 1915.

twenty-four hours therafter, they were again placed in those compartments and their feces collected. By the eighth day six out of the eight had acid-fast bacilli present in their feces. All of them subsequently developing tuberculosis (as shown by the autopsy report).

The second series of experiments was undertaken for the purpose of investigating whether the acid-fast bacillus is not a smegma bacillus. On August 17, 1914, nine healthy-looking guinea pigs were placed in the aseptic compartments and their feces gathered every twenty-four hours for three successive days and examined for the presence of acid-fast bacilli. In none could any be found. On the fourth day we injected a suspension of tubercle bacilli into their knee-joints, and twenty-four hours after the injection and every twenty-four hours thereafter their feces were again collected and examined for acid-fast bacilli. This time we took the precaution of washing the anus and the surrounding parts with sterile water prior to their being placed in the compartment. By the eighteenth day all of the guinea pigs had shown the presence of acid-fast bacilli in the feces.

The same experiment was repeated on September 19, 1914, with practically the same results. At the autopsy we looked especially for a gastrointestinal lesion to account for the presence of the bacilli in the feces. In none could we detect any ulceration.

On February 24, 1915, we placed two guinea pigs in aseptic compartments and collected their feces for three days. No acid-fast bacilli could be found in any. On February 28 one of them was injected with staphylococci and streptococci and the other with staphylococci alone, and the feces were examined thereafter for the presence of acid-fast bacilli. In none could any be found.

All of those acid-fast bacilli could be grown on glycerin-agar media and attained full growth in from fifteen to seventeen days.

Animal Inoculation.—Ten guinea pigs were injected with glycerin-agar cultures of acid-fast bacilli, gotten from the feces of patients suffering from tuberculosis of the joints. Four were injected in May, 1914, and they died within one week. Six were injected on November 4, 1914, after they had been prepared and their feces studied three days prior to the injection, as on previous occasions. All the six developed tuberculosis. The same acid-fast bacilli were found in their feces.

Deductions from Our Experiments and Animal Inoculations.—(1) That the acid-fast bacillus found in the feces is a tubercle bacillus. (2) That it is a living germ, capable of producing the disease when injected into animals. (3) That no matter how the bacillus is introduced into the system it will make its appearance in the intestinal tract and be discharged in the feces without necessarily producing a pathological lesion in the intestinal mucous membrane.

Staining Technique.—The following method of staining and counterstaining was used in our work in all but the first three cases, and we found that the tubercle bacillus is the only bacillus that will remain red while all others will be decolorized and will subsequently take on the counterstain:

1. Cover smear with carbol-fuchsin for two minutes, heat, and keep moist and wash off excess of stain with water.

2. Apply nitric acid, 25 per cent. solution, for two seconds, then pour off the excess and apply.

3. Alcohol (80 per cent.) on slide and leave it on for at least one minute. Then wash the slide with water and apply.

4. Methylene-blue stain for twenty seconds; wash off with water and dry between filter papers.

One may also substitute gentian violet for the methylene-blue as a counterstain and leave same on for two minutes.

The Clinical and Diagnostic Significance of the Presence of Tubercle Bacilli in the Feces.—In order to study its clinical and diagnostic importance it was necessary to select (*a*) cases suffering from positive joint tuberculosis as seen by the symptoms and signs pathognomonic of the disease, aided by *x*-ray and other laboratory tests, or as shown by the subsequent history, bearing out the early diagnosis. (*b*) Cured cases of sure joint tuberculosis. (*c*) A number of cases suffering from diseases other than tuberculosis as controls, also dubious cases.

The result of this investigation was as follows: Active tuberculosis of joints, 42; tubercle bacilli in feces, 30; tubercle bacilli in urine, 2. Cured cases of joint tuberculosis, 6; tubercle bacilli in feces, 0; tubercle bacilli in urine, 0. Dubious cases of joint tuberculosis, 9; tubercle bacilli in feces, 1; tubercle bacilli in urine, 0. Of the dubious cases 3 turned out to be luetic infections; 1 was found to be suffering from a gonorrheal arthritis; 1 was shown to be an ordinary sprain of the knee-joint; 2 cases are still doubtful; 1 case was lost sight of. The patient in whose feces acid-fast bacilli were found turned out to be suffering from tuberculous (active) arthritis of right hip. Control cases 18; tubercle bacilli in feces, 0; tubercle bacilli in urine, 0.

The above figures show that under normal conditions there are no acid-fast bacilli in the feces, also that only in active cases of joint disease are they present in the alvine discharges, and not in cured cases, and therefore the finding of the acid-fast bacilli in the feces in cases suffering from an active disease of a joint, and no active tuberculosis of any other part of the body, is of great significance in reaching a diagnosis in an obscure case.

Location of disease of those in whose feces acid-fast bacilli were found: Hips, 15; spine, 6; knee, 6; shoulder, 1; sacroiliac, 2; foot, 1; total, 31.

Age of the patients with active joint disease in whose feces acid-fast bacilli were found: Youngest, 2 years; oldest, 40 years.

Duration of disease of active cases with presence of acid-fast bacilli in feces: Shortest, 3 weeks; longest, 5 years.

Method Followed in Obtaining Specimens of Feces.—The patient was given a mild laxative, such as castor oil or magnesium citrate solution, the night before collection, and he was ordered to defecate into a chamber-vessel that had been thoroughly cleaned and then placed in boiled water. The feces were then to be put into a newly purchased fruit preserving jar, which had been thoroughly cleaned and then sterilized in boiling water. The feces from 2 to 3 consecutive days were collected in the same manner and put into separate jars and labeled with name of patient and date of collection.

A small amount of the suspected feces was diluted with an equal amount of sterile distilled water to which a few drops of carbolic acid solution (4 per cent.) had been added. The entire mixture was allowed to stand for 12 hours. The water was then poured off very carefully and a small piece of the mucoid, cheesy-looking sediment picked up with a sterile platinum wire loop, placed upon a clean slide, and stained by the method described above.

From each specimen of feces 10 to 12 slides were prepared and a number of cultures made. The cultures were examined from the 15th to the 21st day and some of these cultures were injected into guinea pigs.

The following illustrative cases are reported:

Case I.—R. R. Seven and a half years. United States. Tuberculosis of right hip, duration three and three-quarter years. Regarded as cured and to be discharged from hospital. Examination of two specimens of feces showed tubercle bacilli present in both smear and culture. Treatment by support continued and patient kept under observation.

Case II.—M. M., eight years, Russia. Tuberculosis of left knee, four years' duration. Apparently cured with marked flexion deformity. Feces examined prior to corrective manipulation. No acid fast-bacilli found. On July 16, 1914, his knee was straightened by the "reverse leverage method," at the Polyclinic Hospital. Four days later his feces were again examined and tubercle bacilli found. Cultures were also made and injected into a guinea pig and the pig developed tuberculosis. The disease of the knee which had been quiescent until the manipulation, again became active and has been running an acute course ever since.

Case III.—B. K., twenty-four years. Female. Russia. Clinical diagnosis: Sciatica. Treated for same for nine months by various physicians and also orthopedic surgeons. Due to obscure symptoms and signs. Examination of feces in April, 1914, tubercle bacilli found in cultures. Subsequent history that of sacroiliac tuberculosis.

Case IV.—H. S., four years; male; United States. Patient at Roosevelt Hospital, May 15, 1914. Clinical diagnosis, tuberculosis of left hip joint(?) of three weeks' duration. Past history: Had measles at age of sixteen months; whooping cough at three years, lasting until six months ago. Present history: Three weeks ago mother observed that the child limps and two days ago the child began to complain of pains in the left knee. Has no night pains. Examination showed left knee normal, motion of left hip limited, due to spasm of muscles, gluteal fold shallow on left side. No atrophy of muscles of thigh. *X*-ray negative. Urinary examination, normal. Feces examination, tubercle bacilli present. Subsequent history, that of tuberculous hip and treated accordingly.

Case I illustrates the prognostic importance of the feces examination in cases suffering from joint tuberculosis prior to their being discharged as cured.

Case II leaves no doubt as to the intimate connection between joint tuberculosis and tubercle bacilli in the feces.

Case III illustrates its value in differential diagnosis.

Case IV shows the value of the examination of the feces for tubercle bacilli in very early cases for diagnostic purposes.

Before proceeding with our further remarks and conclusions it might be interesting to give the conclusions of other investigators in that field.

D. M. Alexander, after having studied a number of specimens of feces taken from normal individuals and having found them all negative, and the feces taken from 74 cases of certain tuberculous cases and found 52 specimens positive, concludes: (*a*) "That all acid-fast bacilli in the feces are tubercle bacilli. Acid-fast oval bodies are found frequently but their nature is unknown. (*b*) That there is an intermittency in the appearance of the tubercle bacilli in the feces which may be connected with the flow of bile. This explanation is supported by the action of the cholagogue calomel."

Whether or not the intermittency in the appearance of the tubercle bacilli in the feces is connected with the flow of bile we are unprepared to say; the fact, however, remains that the presence of the tubercle bacilli in the feces one day does not make it certain that one is going to find them in the feces of the following day. To illustrate:

1. Th. B., nine years. Polyclinic Hospital. Tuberculosis of left hip. First specimen of feces 3/24/14 tubercle bacilli absent; second specimen of feces 7/24/14 tubercle bacilli present.

2. B. K., twenty-four years, female. Polyclinic Hospital Tuberculosis of sacroiliac joint. First specimen of feces 4 6/14 tubercle bacilli present; second specimen of feces 8/22/14 tubercle bacilli present; third specimen of feces 8/23/14 tubercle bacilli absent; fourth specimen of feces 8/24/14 tubercle bacilli present.

3. K. P., three years. Roosevelt Hospital. Tuberculosis of right knee. First specimen of feces 5/22/14 tubercle bacilli present; second specimen of feces, 8/24/14, tubercle bacilli absent; third specimen of feces, 8/25/14, tubercle bacilli present; fourth specimen of feces, 8/26/14, tubercle bacilli present.

Viewing our negative findings in the feces with the presence of active disease of the joint from that angle, we cannot but feel that the percentage of the presence of acid-fast bacilli in the feces is much greater than what we have been able to ascertain. The only reason for its absence may be the fact that we gathered the specimens at an inopportune time.

Laird, Kite, and Stewart as a result of experiments and of examinations of a number of cases come to the conclusion that: (1) Nearly all patients with tubercle bacilli in their sputum also have virulent tubercle bacilli in their feces. (2) Very few persons who do not have tubercle bacilli in their sputum have acid-fast bacilli in their feces.

Our own clinical investigations and experimental work convince us that the conclusions of Laird, Kite, and Stewart are incorrect, for the following reasons: (*a*) All the guinea pigs infected by us with tubercle bacilli, no matter through what channel, discharged tubercle bacilli in their feces. Some as early as the fifth day following the injection. In very few of them could we find pulmonary involvement at autopsy, or the presence of intestinal ulceration. (*b*) Most of our patients whose feces showed the presence of acid-fast bacilli had a thorough physical examination. Dr. O. S. Wightman of the Polyclinic Hospital examined a number of them, some were examined by Dr. A. Bassler, others by Dr. E. Bishop. In only 2 of the cases could an apical involvement be found, and only one had tubercle bacilli present in the sputum. It is also a known fact that very few patients with joint tuberculosis have pulmonary phthisis.

Dr. A. J. Quimby has also been kind enough to *x*-ray the chest of a number of our cases, in order to see whether he could detect any lesion in the pulmonary region. With the exception of a few calcareous glands, which are found in normal chests, the findings were negative.

In view of the above facts we feel confident to assume that it is not at all necessary to swallow the sputum containing tubercle bacilli in order that they should appear in the feces. It seems to us more plausible to say that the presence of the tubercle bacilli in the feces of patients suffering from active tuberculosis is due to the fact that the body, being in good condition with resisting power, is trying to rid itself of the foreign invasion by discharging some into the bowels. This theory is borne out by the fact that we have observed that the feces taken when the animals were very ill were very often negative for tubercle bacilli, and when they began to improve the tubercle bacilli reappeared in the feces.

Some guinea pigs stopped discharging tubercle bacilli in their feces a few days prior to their death.

In human beings we have observed the same peculiarity, viz., that when the patients were very ill the feces were negative for tubercle bacilli, and when they improved in general health the tubercle bacilli again reappeared. Whether or not this theory is correct remains to be seen. It sounds reasonable.

RECORD OF CASES

Active Cases of Tuberculosis

and we shall make it our business to test its validity in our future investigations.

Conclusions.—1. The acid-fast bacillus resisting decolorization with 25 per cent. nitric acid watery solution, followed by 80 per cent. alcohol, is a tubercle bacillus.

2. Patients suffering from joint tuberculosis keep on discharging tubercle bacilli for years, so long as the disease is active.

3. Those bacilli are alive and capable of producing tuberculosis in others, as proven by animal inoculation.

4. In obscure joint conditions the finding of tubercle bacilli in the feces may be of great diagnostic importance and should never be neglected.

5. A patient suffering from joint tuberculosis should not be discharged as cured without a thorough search for acid-fast bacilli in the feces, and if they are found, the patient should be kept for further observation, for it shows that there is still some activity of the disease present.

6. The smegma bacillus is conspicuous by its absence in the feces.

7. We fully agree with the remarks of Dr. M. Solis-Cohen that "The feces of tuberculous patients must be regarded as a source of contagion and must always be thoroughly disinfected. The same precautions in regard to disinfection of hands, clothing, bed covers, etc., soiled by fecal evacuations, that are taken in cases of typhoid fever should be observed in the management of patients with tuberculosis." To all those who have taken some part in this work and to those who have helped us elucidate difficult points, we wish to express our gratitude.

The Action of Aconites.—Alfredo Chistoni has studied the effects of the action of aconite upon the cardiovascular and respiratory systems. In the frog small doses of crystallized aconitine or of the fluid extract of aconite cause a slowing up of the heart beat dependent upon the prolongation of the ventricular systole, while larger doses produce a prolongation of the diastolic period. In the dog the subcutaneous administration of aconitine or of the fluid extract of aconite diminishes the rate of the heart beat and the blood pressure, as the result of the excitation of the cardio-inhibitory center and the inhibition of the vasoconstrictor center.—*Giornale Internazionale delle Scienze Mediche.*

SYMPTOMATIC PSYCHOSIS OF RENAL TYPE, WITH REPORT OF TWO CASES.

By EMANUEL S. BRODSKY, M.D.,

WESTPORT, CONN.

ASSISTANT SUPERINTENDENT OF THE WESTPORT SANITARIUM; FORMERLY ASSISTANT OF THE STATE PSYCHIATRIC INSTITUTION IN THE CANTON OF LUZERNE, SWITZERLAND.

THE contact between psychiatrists and general practitioners is to be found in the field of those mental disorders which are definitely dependent on a specific physical disorder. Among these, infectious and autointoxication psychoses take the first place and represent the greatest part of symptomatic psychoses. It is also becoming more and more clear that we cannot trust entirely to purely clinical pictures for the diagnosis of mental diseases, and a study of symptomatic psychoses will aid in the task of differential diagnosis, proper treatment, and correct prognosis.

The specificity of the symptoms of the symptomatic psychosis is one that is still debated, and it will require extended investigation before we will be able to recognize the various syndromes of the symptomatic psychoses. The object of this paper is to illustrate the association of fear psychoses with functional disturbances of the kidneys.

We know that the functional disturbances associated with uremic conditions are products of an autointoxication, the result of retention in our body of certain elements which are usually eliminated by the kidneys. The cerebrospinal symptoms of uremia, which we observe every day, are delirium, convulsions, coma, headaches, etc. Melancholia and delusional insanity with ideas of persecution due to uremia are rare. There are evidently some other forms of mental disturbance which are also due to a disturbance of the functions of the kidneys. The different pictures of the same autointoxication are probably due to two factors; either the intensity of the fixation of the poison to the nerve cells, or injury of different elements of the nervous system.

From experience it is known that the "selective affinity" between the cells of the nervous system and certain poisons of endogenous as well as exogenous character, is greater than that of the cells of other organs; that the nervous system contains an amount of toxin greater than any other part of the body; that certain toxins increase their virulence when combined with the nerve tissue, for instance, tuberculin when mixed with nerve tissue has its power increased as much as fourfold. The clinical difference of the symptoms in poisoning with parasitary toxins is thus dependent on the intensity of the fixation of the poison to the nerve cells, and the same could be said about other toxic conditions of our nervous system. This can be illustrated by the following observations: Alcoholic intoxication, which produces exhilaration in one person, melancholia in another, induces motor incoordination or staggering in a third, or alcoholic polyneuritis, is in many cases not accompanied by mental disturbances, while in others it produces the so-called polyneuritic psychosis. Influenza produces in one melancholia, in another mania, in a third sensory deliria and in a fourth polyneuritis.

To the psychoses due to autointoxication belong those appearing in uremia, cholemia, hydrops, cachectic processes in pernicious anemia, diabetes, eclampsia, and similar processes.

The symptomatology of these various forms of

symptomatic psychoses is manifested in the form of deliria, epileptiform excitements, dazed and stuporous conditions, hallucinatory and catatonic conditions, and incoherent amentia.

Bonhoeffer calls attention to the fact that epileptiform excitement due to toxic infection need not differ in any way from a real epileptic one. The same may be said of many catatonic and amentia pictures. Referring to the same author, it may be said, that according to the conditions of present-day experience, we must accept autointoxication as the most probable cause of many processes, even when the nature of the diseased organs is as yet quite unclear. A number of such cases passed through the Westport Sanitarium during the year 1914. I have selected two which are representative of this class and the most instructive.

Case I.—Mrs. F. K., fifty-eight years of age, entered this institution July 14, 1914, at 6 p. m. She had been arrested at home in a very excited condition, was destroying everything and aggressive to everybody who approached her. She was first taken to jail, and a few hours later brought handcuffed to this institution by two police officers. Patient was always temperate and had been working as a canvasser up until two o'clock of the same day. The attending physician reported that she had been treated a year and a half ago for Bright's disease. Granular and hyaline casts were found in the urine with traces of albumin, and the ophthalmoscopic examination revealed a retinitis albuminurica. Upon entering the institution she was constantly crying, saying: "Oh, everything is gone." Expression of fear was evident. While in the institution she had visual hallucinations, expression of fear and despondency, was semi-oriented for time and place and partially for person. Thought she saw a naked man with a rope in his hand. Was coherent. At times covered her eyes, thinking she would escape from the terrifying visual hallucinations. When asked if she saw things in her room, she replied "Yes"; but when asked for verification did not give correct answers. When shown keys and asked what they were, she said "Money," and started to cry: "Oh, my money! He took the money!" When asked who, she replied: "The naked man." Complained of headaches, did not sleep, pulse accelerated, blood pressure 170, appetite poor, anemic. Urine, sp. gr. 1,008, acid reaction, traces of albumin, a few hyaline casts, sugar negative. Ophthalmoscopic examination showed retinitis albuminurica. Lateral nystagmus occurred several times periodically when the patient was more restless and excited. (Low diet and warm baths.)

July 17—Same fear condition, nystagmus, crying, partially oriented for time, place, and person, complained of headache, visual disturbances and could not see objects distinctly. Pupils medium size. Blood pressure, 170. Urine pale, sp. gr. 1,008. Urea, 4 grains per ounce; daily quantity of urine, 55 ounces. Lamenting, depressed, and did not remember the day of the week or when she came here.

July 24—Headache, vomiting, visual disturbances, slept better, depressed and lachrymose.

July 25—All the symptoms subsiding, visual hallucinations disappeared and no fear. General condition improved. Urine, sp. gr. 1,016, acid reaction, no casts, no albumin. Urea, 7 grains per ounce. Daily quantity of urine, 55 ounces.

Case II.—Mrs. D. W., thirty-eight years of age, entered this institution November 6, 1914. She had left Mercy Hospital, Springfield, Mass., the same day. Patient had scarlet fever when a child. Six years ago she was "swollen all over the body." Married three years ago, no children. A year and a half ago she had symptoms of a phantom pregnancy, distended abdomen, and prepared everything to meet parturition and the new condition of a mother. Headaches for a long time before the sickness came on. Four weeks ago she became suddenly excited, confused, and did not recognize her surroundings. The diagnosis made in Mercy Hospital reads: "Acute mania." Confused most of the time, irrelevant, did not recognize people, and talked constantly to herself. Patient was always nervous and timid. No mental or nervous diseases in the family.

While in the institution she did not know her age or the date of her birth, was relevant and coherent. Expression of fear, restless, and was afraid somebody was grabbing her. Said she heard children crying and that they were locked in the cellar. She was afraid they would die. Oriented for place and person and partially for time. Did not recall remote events; memory for recent events good. Fear, illusions, and acoustic and visual hallucinations. Could not sleep because she thought loaded guns were under her bed and feared everybody was going to be killed.

Physical status: Pale, poorly nourished, dry lips, coated tongue, pulse 100-110, unequal, soft. Reflexes preserved. Complained of pressure in head. Uranalysis: sp. gr. 1,010, slightly acid, no sugar or albumin.

November 10—Very restless and fearful. Tried to suffocate herself by tying a handkerchief around her neck. Ate only when urged, but took sufficient food. Uranalysis: sp. gr. 1,006, neutral reaction, pale color; urea, 1 grain per ounce; daily quantity of urine, 55-60 ounces; no albumin.

November 18—Mental condition the same. Uranalysis showed the same results.

November 20—Patient restless, at times better, slept only with hypnotics. Tried to suffocate herself again. Fearful acoustic hallucinations.

November 24—Not so restless and less fearful. Sp. gr. of urine 1,018, no albumin; urea, 3 grains per ounce. Daily amount, 50 ounces.

November 28—Mentally and physically better. No evidence of hallucinations.

December 14—Patient constantly improving, fear subsiding, started to sleep well, and no headache. Urine: sp. gr., 1,022, light color, acid reaction; urea, 8 grains per ounce; daily quantity, 50-55 ounces. Discharged December 17, 1914, entirely free from fear and in good physical condition.

I saw this patient again on May 21, 1915, five months after she was discharged as cured. She reported that she had felt cheerful all the time and all right physically. Lately she had had headache and insomnia again, but it was not so bad as before the sickness. Pulse 80, blood-pressure 170-175. Uranalysis again showed pale color, specific gravity 1,009, acid reaction, albumin and sugar negative. Amount of urea 2.5-3 grams per ounce. Daily quantity 45 ounces on liberal diet. Microscopic picture negative. I again ordered strict milk diet and warm baths. One week later patient reported that she slept better and felt better generally.

In both cases Bright's disease occurred long before the onset of the psychoses. In the second case the first attack dated probably from childhood when she had scarlet fever. The onset of the psychosis in both cases was acute with no signs of any current infectious disease or alcoholic intoxication. Family history negative in both cases. The neuropathic constitution in the second case was evident. Neither had ever been affected with any mental disease. The psychoses lasted a short period, two and eight weeks respectively. Rapid improvement and complete recovery took place after a milk diet and warm hydrotherapeutic applications. The improvement of the urinary findings, specific gravity, and amount of urea, occurred simultaneously with the improvement of the mental condition.

The mental condition in the first case presented the picture of a fear psychosis with slight ideas of persecution, aggressiveness and a tendency to destructiveness. In the second also a fear psychosis with a strong tendency to self-destruction. There were no symptoms of cerebrospinal irritation, which we meet in uremia, except headaches, pressure in the forehead, nystagmus, and increased blood-pressure in the first case. The consciousness was not clouded as we see in uremic delirium.

Discussing the uranalysis, we see in the first case the picture of a chronic interstitial nephritis. In the second case we did not find any albumin or casts, but a persistent low specific gravity, 1,006-1,010, and an unusually low amount of urea, 1/5 per cent. in 55-60 ounces of urine in 24 hours.

According to the latest work of Marshal and David in biochemistry, an amount of urea lower

than 1 per cent. indicates a retention of urea in our body. This is a regular occurrence in certain cases of severe nephritis when for any reason the excretion of urea is prevented, and it would appear that the entire amount formed is stored in the body, as there is no evidence of the conversion of urea into other substances. The probable diagnosis in the second case, taking into consideration the history, is also chronic interstitial nephritis.

A fair conclusion from the above consideration is that one deals here with mild physical symptoms, as a result of disturbance of the renal function. The mental picture could be classified as a fear psychosis, which could be considered as a symptomatic psychosis, due to a disturbance of the function of the kidneys. On the diagnosis depends the treatment and prognosis.

SUBDELTOID BURSITIS*.

By S. KLEINBERG, M.D.,

NEW YORK.

CHIEF OF ORTHOPEDIC DEPT. LEBANON HOSPITAL DISP., CLINICAL ASST. IN N. Y. HOSP. FOR RUPTURED AND CRIPPLED AND ORTHOPEDIC DEPT. OF MT. SINAI HOSPITAL.

THE stiff and painful shoulder is a very frequent sight in an orthopedic clinic. The diagnosis of its exact etiology, however, is, in a given case, not very common. Of the many types of shoulder disability, that due to subdeltoid bursitis, so ably studied by Allen, Baer, Rugh, Littig, and especially Codman of Boston, has received insufficient attention at the hands of the profession in general. One often sees a stiff and painful shoulder diagnosed as rheumatic, and the patient, suffering intensely from pain which can easily be relieved by proper splinting, is for days and weeks given aspirin or other salicylate compound. Not infrequently subdeltoid bursitis in its chronic stages on account of presenting such symptoms as pain, stiffness, and atrophy of the shoulder, is mistaken for an arthritis, tuberculous arthritis, and consequently inappropriate treatment applied, when a careful examination would definitely demonstrate that there is no intra-articular disturbance. It is with the hope of emphasizing the clinical picture of subdeltoid bursitis producing shoulder disability that I present to you the following series of patients studied during the past three years.

Anatomy.—A word about the anatomy of this bursa will I think not be amiss. It is located over the anteroexternal surface of the shoulder joint, directly under the deltoid muscle, extending up under the acromion process about ¾ inch, and downward half way along to the attachment of the deltoid to the humerus. Its base is intimately attached to, and in fact formed by, the insertions of the supraspinatus, infraspinatus, and teres minor muscles. Roughly speaking the bursa is about two and a half inches in diameter. Like other bursae, it contains normally just enough fluid to allow easy motion of the parts on either side of it.

Etiology.—Situated over a joint that is used so frequently, and in such an exposed position, the subdeltoid bursa is subject to an unusual variety of traumata as a blow on the shoulder, a fall, excessive activity of the shoulder, etc. It is therefore not surprising to find this bursa frequently injured. Also from its position over the external rotators and the supraspinatus and under the deltoid, one realizes that abuse of or injury to these muscles must have a traumatizing influence on the delicate living membrane of this bursa, and vice versa than an inflamed bursa will from its proximity to these muscles limit their activity. In addition to direct injury, the bursa may be affected by such conditions as prolonged fixation following operations, fractures or dislocations in or about the joint and infection, suppurative[1] or non-suppurative, as rheumatic or influenzal.

Pathology.—The pathological changes in this condition affect three structures. First, *the lining membrane of the sac,* which may be only congested (giving us the acute painful stage), or moderately or markedly thickened (as in the chronic stage). In one of Baer's[2] cases, the wall of the bursa was 1 cm. thick. Secondly, *the contents of the bursa:* The sac may contain, especially in the early stages, a small amount of fluid which is rarely recognizable on ordinary examination, or it may be markedly distended, as in several of my own cases. The fluid is usually serous, but may, as in one of my patients, be sanguineous. Synovial villi may become organized into fibrous bands early, connecting the opposing surfaces of the bursa, and these frequently become strong and thick, and a serious hindrance to the normal function of the shoulder. In one of Codman's specimens[3], typical limitation of motion was found after all muscular attachments were cut, due to adhesions. Thirdly, the *bone under the capsule:* Changes (demonstrated by radiograms) seen here occasionally, are due presumably to the causative agent as a trauma, simultaneously affecting the bone. Not infrequently one sees a streak of calcareous deposit along this bursa. Codman and Brickner believe this always to be subbursal. The greatest interest in this connection attaches to calcareous deposits in the region of attachment of the supraspinatus tendon. Codman cites five dissecting-room specimens in which there was a condition leading him to believe that the supraspinatus tendon had been partially torn away from its attachment to the greater humeral tuberosity. He also presents *x*-rays of cases of trauma of the shoulder, showing evidence of a chip of bone from the tuberosity torn off at the insertion of the supraspinatus. The same author reports two cases which gave a history suggestive of detachment of this muscle; in both operation confirmed the diagnosis, and suturing the tendon produced a prompt recovery. Brickner has operated on eight cases of subacromial (subdeltoid) bursitis that showed radiographic shadows of lime deposit, and removed variable quantities of calcereous matter from within or about the tendons of the supra- and infraspinati muscles. The writer has not seen any instances of undoubted uncomplicated ruptured supraspinatus tendon, but has often noted radiograms showing a calcareous deposit at the site of attachment of the supraspinatus, where, however, there was no disturbance of the function of that muscle, nor any history of trauma or severe exertion. In fact most of my cases with radiograms showing a calcareous deposit in the vicinity of the subdeltoid bursa gave no history of any injury.

*Read before the Lebanon Hospital Alumni Society, Jan., 1915.

In a recent article on shoulder disability Brickner[3] states that in his personal experience none of the patients with lime deposits were relieved of pain by any method, except those operated upon. The writer takes exception to this, because he has seen a goodly number of painful acute and subacute cases of subdeltoid bursitis showing shadows of lime deposit, and all the patients recovered under conservative treatment. So that while perhaps operation may be advisable to hasten recovery, it is not indispensable, and in the majority of instances, at any rate, in the writer's experience, the presence of a calcareous deposit in a case of subdeltoid bursitis does not preclude complete relief from pain and recovery from disability under non-operative methods.

The limitation of motion in the early stage is due to reflex spasm because of extreme sensitiveness of the bursa, which holds in check all motions but especially abduction and rotation. Let me emphasize that limitation of motion is never complete, though it may be very marked in abduction and rotation. In the later stages, motion is limited by the fibrous adhesions. Such bands have been demonstrated by Codman, Baer, and others during operative procedures instituted for the relief of the limited motion.

Course.—The usual history one obtains is, that a middle-aged man or woman, mainly of the laboring class, having received an injury, as a blow on the shoulder during a fall or a strain in lifting a heavy weight, or in overreaching for some object, experiences some pain in the shoulder which gradually gets worse and in the course of a few days (sometimes in several hours) becomes excruciating. At about this time the limitation of mobility of the shoulder sets in. The pain, almost always more severe at night, may be confined to the region of the shoulder or may radiate to the fingers or up into the neck. As yet there is no satisfactory explanation for this shooting pain. I would here call attention to the fact that frequently there is no history of any definite injury or strain, the condition beginning suddenly, as on awakening in the morning, or arising insidiously as a discomfort in the shoulder, gradually reaches the acute painful stage above noted, in which pain and disability are the chief symptoms. The pain persists for two or three weeks, after which there is a slow and usually certain progress to recovery. The course may extend over a period of five or six weeks to as many months, rarely two or three years, depending on the severity of the affection and the treatment instituted.

The patient usually presents himself to the physician holding his arm at the side, guarding very anxiously against any jarring or motion of the shoulder. In about 10 to 15 per cent. of the cases one observes a definite swelling in the region of the bursa; this has a circular outline and in the early stages is sensitive to touch. Dawbarn's sign (tenderness over the point of the shoulder disappearing when arm is abducted) is occasionally observed more particularly in the acute stage. It must be evident that actual swelling is present more often than seen, as a slight distension of the bursa in a muscular or obese individual would not be discernible under the large fleshy deltoid. There is never any local fever. All voluntary motions are carefully performed; flexion, extension, and adduction are free, but abduction and rotation are all but completely limited. Passive motion too is definitely limited in abduction and rotation. Again I wish to emphasize that motions are only limited and none completely lost. If the condition has existed for at least several weeks, one invariably finds an atrophy of the muscles on the posterior surface of the scapula. Neurological examinations made in at least half of my cases have resulted in negative findings.

Differential Diagnosis.—The following important conditions must be taken into consideration in making a diagnosis:

(1) Tuberculous Arthritis: This presents a history of many months or even years of disability; atrophy of arm; *limitation of motion in every direction;* *x*-ray shows destruction of bone.

(2) Fracture of Humerus: Here there is definite history of injury; evidence of fracture; *x*-ray shows the break.

(3) Axillary Abscess: A finger applied to the axilla will detect a hot, tender area; there is general constitutional disturbance and fever. I have had one such case where the disability and shoulder pain in a strong young man, lead to the diagnosis of bursitis. The arm was held to the side so tightly that it was impossible to examine the axilla. However, the fever and sensitiveness near the axilla, and absence of any deformation or tenderness over the bursa made the diagnosis evident.

(4) Muscular Rheumatism: This condition affects more than one part of the body at the same time, and is usually referred to the fleshy part of the muscles; there is an absence of the definite limitation of motion present in bursitis.

(5) Acromioclavicular Arthritis shows local swelling and tenderness that render its recognition easy.

(6) Circumflex Paralysis produces a *complete* loss of abduction, with absence of any pain and no loss of the shoulder motions.

(7) Tenosynovitis of the Biceps Muscle produces a swelling that extends along the front of the upper part of the arm; there is a disturbance in the function of the biceps[4] which is absent in bursitis.

(8) Brachial Neuritis: In this condition the pain is more general and accompanied by weakness or paralysis of muscles definitely limited to a certain nerve or group of nerves.

(9) Tumors: These when affecting the bones are not hard to recognize, as the *x*-ray makes the diagnosis simple.

(10) Periarthritis of the shoulder: This term in the past has been a very convenient name for a large number of obscure conditions about the shoulder. Occasionally one sees a shoulder that following a severe exertion or hurt is painful, generally sensitive with inconstant and irregular limitation of motion. Such a condition, all other causes being excluded, may be considered a periarthritis. Subdeltoid bursitis is a localized periarthritis. In the majority of instances, however, close examination will reveal a bursitis, tenosynovitis, myositis, neuritis or some other definite condition.

Treatment.—As previously suggested one may conveniently divide the course of this affection into the first or painful stage, and the second stage when disability is the most prominent symptom and claims our attention. In the first stage, rest is all important. We agree with other observers that the ideal position for the arm is extreme abduction,

in which condition there is least strain on the bursa, and whenever possible this should be carried out. However, for the average patient, and particularly in dispensary practice, this is a most impractical attitude. Moreover we usually find the patient with the arm held tightly against the body, and it would be very painful to abduct the arm except under an anesthetic; hence as a routine procedure we leave the arm in the position it is found, splinting it with adhesive plaster or plaster-of-Paris bandages, until the painless or second stage appears. During this time, a sedative may if necessary be administered.

In the second stage we find that the arm is held down by bursal adhesions of greater or less firmness, and the treatment consists of gradually stretching these under or frequently without an anesthetic, being sure not to stretch the shoulder too vigorously at any one sitting. The patient is carefully instructed in the proper exercises to perform at home to hasten recovery. Such are frequent attempts to reach the back of the head, or clasping hands behind the back, or grasping some object above the head and lowering the body.

When the adhesions are of long standing and confirmed or in order to shorten the period of convalescence, excision of part of the bursa may be done with impunity and rapid relief.

Case I.—Rachel R. (Dr. Nathan's Clinic at Mt. Sinai Disp.) Housewife; age 46. Seen first in the summer of 1912, when she gave the history of gradual onset of pain in the left shoulder two months previously. No history of injury or any illness. Three to four weeks after onset of pain, shoulder became stiff. Examination found the patient holding arm tightly to side of chest, could slowly flex and extend the arm, but could neither raise nor rotate it. Manipulation showed marked restriction of abduction and outward rotation. No swelling over shoulder, marked tenderness over the head of humerus. *X*-ray showed shadow near the great tuberosity.

Treatment: Arm supported by means of adhesive plaster shoulder cap for several weeks. Pain having subsided the arm was stretched three times a week at the clinic, and patient instructed to use the arm frequently at home. Complete recovery in two months.

Case II.—Paul C. (Dr. Nathan's Clinic case No. 1387.) Tailor; age 31. First seen Sept. 14, 1914. Pain and stiffness in right shoulder began one month ago, no history of injury or preceding illness. Examination: Arm held at side, distinct swelling and tenderness over region of bursa. Abduction limited beyond 30°, outward rotation almost completely limited, other motions free to about half of normal extent; *x*-ray negative.

Treatment: Adhesive plaster shoulder cap for five days when pain having greatly subsided stretchings were begun and continued three times a week. One month after first visit, showed absence of any swelling, motions unrestricted and patient back at his work complaining only of an occasional pain in the shoulder.

Case III.—Harry S. (Referred by Dr. Henry Heiman.) Clerk; age 29. First seen Sept. 3, 1914. No history of injury. Onset eight days ago with pain in left shoulder; pain became worse and three days afterward stiffness set in. Examination: Arm held at side, distinct swelling, size of silver dollar, over front of shoulder, tender and fluctuating. Abduction painful and limited beyond 20°; outward rotation almost completely restricted; other motions absolutely free.

Treatment: Adhesive plaster shoulder cap for ten days at end of which time the swelling and sensitiveness were gone. Shoulder massaged and manipulated. Oct. 11, 1914, shoulder normal in appearance and function.

Case IV.—Rose S. (Author's clinic at Lebanon Hospital.) First seen March 23, 1914. Housewife; age 50. Gradual onset during period of several weeks of pain and stiffness in left shoulder. Examination: Distinct swelling over outer part of shoulder; no local heat, slight sensitiveness, abduction and outward rotation limited about half of normal extent; other motions free. *X*-ray shows no bone lesion.

Treatment: Adhesive plaster shoulder cap for several weeks, then massage and manipulation three times a week for two months at end of which time patient was free from all pain, and motions entirely unrestricted.

Case V.—Elizabeth P. (Author's clinic at Lebanon Hospital.) Housewife; age 50. First seen Nov. 11, 1914. Five weeks ago, after a hard day's washing and after lifting a pail of water with the left hand, she experienced a sharp pain in left shoulder; pain worse on attempted motion. She gradually got better but the condition recurred two days ago. Examination: Slight swelling and marked tenderness over outer and upper part of left shoulder, directly under the acromion process. Dawbarn's sign positive. Abduction limited beyond 40 or 50°; external rotation limited to about one half; other motions free.

Treatment: Adhesive plaster shoulder cap applied Nov. 18, 1914. Pain has subsided. Patient can move arm freely in every direction except outward rotation, which is still slightly limited. Swelling gone, tenderness much diminished.

Case VI.—Annie S. (Author's clinic at Lebanon Hospital.) Scrubwoman; age 45. Seen first, Sept. 15, 1914. Three weeks ago after a hard day's work, right shoulder became painful; this grew worse and in the course of a few days, a swelling appeared and shoulder stiffness set in. Examination: There is a large tender fluctuating swelling, over the outer surface of the shoulder. All motions are free excepting outward rotation and abduction, which are painful and restricted to half of their normal extent.

Treatment: This patient being especially anxious for rapid relief, an incision was made, under local anesthesia, into the bursa. A large blood clot and tabs of tissue were removed. The sac was explored and found to be about three inches in diameter and extending under the acromion process, the bursal wall was not thickened. The wound was closed and the patient made a prompt recovery. The contents examined by the Lebanon Hospital Pathologist, Dr. E. P. Bernstein, were reported to consist of red blood cells, many pus cells, and masses of fibrin.

Case VI.—Benjamin S. (Dr. Whitman's clinic.) Jeweler; age 53. Seen first Jan. 6, 1914. No history of injury or previous illness. Present trouble began three weeks ago with pain in the right shoulder which gradually got worse; was able to move arm until three days ago since when he cannot raise his arm, and the pain is so severe that it keeps him awake at night. Examination: Man is evidently in pain; holds arm against his side and guards anxiously against any sudden motions. On being coaxed, he flexes, extends and adducts the arm but the other motions are limited. Passive motion limited only in abduction and outward rotation. Exquisite tenderness over head of humerus. Dr. N. Sharpe reports neurological examination to be negative, *x*-ray negative.

Treatment: Adhesive plaster shoulder cap for about four weeks when pain having subsided, manipulation and massage were instituted. There was a gradual improvement and when seen on Oct. 10, 1914, presented a complete cure.

Case VIII.—Harris Z. (Dr. Whitman's Clinic.) Tailor; age 42. First seen Jan. 22, 1914. Three days ago without discoverable cause, he began having pain in the right shoulder, radiating down the arm; the next day the pain was worse and he had to stop work. Examination; Arm at side; over front of shoulder there is a sensitive swelling. Active and passive motions limited only in abduction and outward rotation.

Treatment: Adhesive plaster shoulder cap for several weeks followed by manipulation and massage. Sept. 26, 1914, complete anatomical and functional recovery.

Conclusions.—1. Subdeltoid bursitis is a frequent cause of shoulder disability.

2. It is most often due to some injury, but many cases give no history of any definite trauma.

3. It is represented clinically by pain in the shoulder, partial limitation of abduction and rotation, especially external rotation, and occasionally localized swelling and tenderness; flexion, extension, and adduction are unrestricted.

4. The treatment consists mainly of protection during the painful stage, and manipulation and careful repeated stretchings of the shoulder during the subacute and chronic stages.

5. The presence of a radiographic shadow in the vicinity of the bursa need not in the majority of instances influence the usual course of treatment, and certainly in most cases does not demand operative interference.

6. Operation is indicated only—

(*a*) To shorten the period of convalescence in those patients where time is an important factor, and

(*b*) In chronic cases where the symptoms have not been relieved by conservative methods.

INEBRIATE HOSPITALS.

AN HISTORICAL NOTE.

By T. D. CROTHERS, M.D.

HARTFORD, CONN.

The late Dr. Rush of Philadelphia was the first American physician to urge the organization of distinct institutions for the care of alcoholics in 1809.

In 1830 Dr. Todd of Connecticut urged that the State organize such institutions, the same as insane asylums.

In 1857 the first distinct home for the reception of persons of this class was opened in Boston, Mass. Later it became the Washingtonian Home and has continued as such up to the present. It is the oldest institution in the world for the medical care and treatment of inebriates.

In 1864 the New York State Inebriate Asylum at Binghamton, N. Y., was opened and proposed to treat such persons on broad, scientific plans, allied to that of insanity. This was the great pioneer institution of the world and was projected on a large scale.

In 1875 I became Assistant at this institution. At that time there were eight institutions in existence in different parts of the country, some of them semi-scientific, but all having for their object the restoration and cure of the drink obsession.

Public sentiment was at first very violently opposed to the plan of gathering inebriates and dignifying them as sick and diseased, and medical journals echoed these opinions. The Medical Record was the first of all the journals to show a kindly sympathetic spirit and recognition of the disease of these cases. The opposition was so intense that nearly all the older institutions succumbed. A few, like the Washingtonian Home, which treated the indigent inebriates survived.

In 1878 I was placed in charge of an institution in Hartford, Conn., which, notwithstanding the storms and stress, has continued up to the present. In 1890 a great wave of gold cure hospitals reached their highest point of prominence. At that time there were over 150 different homes, hospitals, and sanatoriums where persons were treated by mysterious, specific drugs and remedies that were guaranteed to cure. A large number of physicians who took this treatment opened homes and began to treat patients on the same basis. The zenith had been reached, and from that time to 1890 there was a steady decline in the number of institutions and the enthusiasm of their defenders. At that time not more than 75 or 80 sanatoriums of all grades existed, in name or in reality. As far as the records can be obtained, in 1910 this number had diminished to less than 30. Like the weak medical colleges, they either joined with other institutions or succumbed.

A number of persons who had lost all their property in promoting ventures of this character turned to selling specific prescriptions to doctors for home treatment. This in some sections was quite prominent and still is. Some of the more daring of these have promoted the "three day cure" and are moving about in different parts of the country promising absolute cure in three days and winning a certain number of patrons who pay prices proportional to the rapidity of the cure.

A few institutions advertised boldly the drugs they used and claimed the results are practically specific. When confronted with the fact that their experience was not confirmed by other observers, they explained it as due to the surroundings and faulty use of the means, by incompetent men.

A few years ago, the state of Massachusetts built a farm colony hospital for this class which has been very successful, not only as an experiment, but as showing the possibilities for larger and more exact work. Iowa did the same thing, and has the second State Hospital for inebriates in active operation.

Several legislatures have passed bills for the formation of State institutions, but none of them have yet materialized. Several large cities have colonies where inebriates of the indigent class are cared for, with more or less success.

There are today about eight institutions where persons of this class are taken exclusively and treated. These are scientific, or semi-scientific, in their management. Some of them combine prayer, pledge-taking, and various other religious influences as methods of treatment. A few are exclusively scientific in their use of only exact means and measures. In the meantime, there are over 150 hospitals, surgical, medical, mental, and hygienic sanatoriums, where such persons are received and treated. In small institutions for mental diseases, the alcoholics and drug takers comprise a large number of the inmates.

In the pauper hospitals of large cities, the inebriate and alcoholic patients are very numerous. In all the large insane asylums wards are assigned for this class. Some of them are overflowing with patients. Small private institutions receive such patients as mental cases. It is estimated that there are fully 5000 patients of this class under treatment in the United States. This includes the paupers of the large city hospitals and in all probability the number is a minimum one.

Physicians who have a large practice find such persons in almost every circle of society. Often they appeal to the physician for help, or else they are secretive and present a group of symptoms which the physician readily traces to alcohol or drugs.

When these persons appeal to physicians where to go, and ask his advice as to probable results, there is a great deal of confusion. First, the physician is not quite sure of the advertising sanatorium. Often their pretensions and claims are more or less suspicious and suggest possible failures.

If he recommends them to private hospitals for

mental diseases, the patient feels that he has been stigmatized in some measure, and classed with those of unsound mind. While the treatment may be very rational and reasonable, there are always shadows in the surroundings, which the patient magnifies.

If he has reached a stage of decided mental impairment and is taken to an insane hospital, the same objections follow and his friends share the idea that he has been injured by contact with others mentally impaired.

If the physician is credulous enough to send the patient to some empirical institution where absolute cures are guaranteed by methods unknown and unexplainable, there are uncertainty and anxiety as to the results. Even when these are apparently good and the patient returns greatly restored and later relapses there is doubt in the mind of the physician as to whether this was the best course to follow.

If the physician should buy specific proprietary drugs, advertised for this purpose, and administer them himself, the results will be about the same. At times they will be favorable, and at others the opposite.

If the physician is stimulated to make a study of these cases, and seeks to find out all the general facts relating to the symptomatology, prognosis, and treatment, there are a certain complexity and undefinable range of causes that work out so irregularly that he becomes easily disgusted and finally accepts the theories of the moralist, that there is a moral element which the clergyman is best fitted to treat.

In all this there is an uncertain grouping of facts and an absence of exact scientific study that fails to indicate the first principles of treatment. It is this condition that has made inebriate hospitals unpopular in a great many ways, and has still further prejudiced public sentiment in the belief that they were failures as medical measures, and could only give first aid treatment.

The irregulars have taught the public that a brief time only is necessary for cure; that beyond this the patient is able to take care of himself. They have also taught the public that notwithstanding their secret methods and irregular means of treatment, there is a degree of curability possible that could hardly be expected.

At one time the gold cures boasted of from 95 to 98 per cent. permanent restoration. Later this was much reduced, and finally after various studies of a large number of persons who had tried these methods it was found that less than 20 per cent. lived lives of total abstinence extending over ten years.

This in comparison with the few hundred cases studied who were under the care of reputable medical men, and who remained under treatment from four to twelve months, is a very poor record. It is the general opinion now, of all persons who have had opportunity to observe carefully, that one in about every three who remains under treatment a sufficient length of time is permanently restored. Of course these figures do not apply to the pauper inebriate who has reached the terminal stage of the disease, but even here some remarkable examples of restoration are seen.

The laws governing the commitment and control of patients are more simple and effective in the State of Connecticut than any other. Massachusetts and Iowa have also very practical laws, making it legal to restrain persons of this class without great publicity.

The reform efforts to limit or abolish the sale of alcohol and the Harrison law making restrictions of the sale and distribution of drugs have brought into prominence a very large number of sufferers and given the question a new interest.

It is clearly evident that the empirical stage of this borderland neurosis, particularly its study and treatment, is passing and the demand now is for well-organized, reputable hospitals for the control and treatment of this class. The business and professional man who is able to pay for services of this kind is looking for the proper organized institution, managed by scientific men, to bring this much-needed relief. A very large number of young men could be permanently restored if sent to some institution and educated hygienically as well as treated medically.

The pauper inebriates who have exhausted all their resources, and are dependent on the public for care and protection, should be segregated in farm colonies and made self-supporting for periods of months and years. There is unmistakable evidence showing that this is the next step in public charities that will occupy a great deal of interest in the near future.

The study of inebriety and alcoholism and their cure and prevention has been growing up steadily through the last half century. It has now reached the scientific stage and the work done in all the private hospitals for this class shows that they are filling a want which cannot be supplied in any other way. There is a field for over 100 institutions in this country, large and small, that if properly organized and carefully managed along scientific rational lines would be constantly filled to overflowing.

The general facts of the etiology and pathology of these cases are known, and the principles of treatment are established along general lines sufficiently broad to enable any student, with any kind of original genius and inspiration, to enter this field and make a success of it.

As in all other fields of medicine, the physician who is trained and adapted constitutionally to study and treat these neuroses is the largest factor in the success. Institutions on the mountains or at the seashore, or in the center of large cities, with equipment and appliances of all kinds, can never be successful unless the proper man is found to manage them.

One of the most notorious of the "cure" promoters was successful wherever he went. He could open an office in the slums of the city and have a crowd of patients, or go anywhere in any place and inspire confidence and faith in sufferers of this class. His skill in building up what he called institutions was so phenomenal that when it reached a very high point of financial success he would sell out and move on. His successor was astonished that the business dropped down so quickly, and could never be restored again. This experience of personal influence and adaptability is seen in every circle of life. Why it is not repeated more often, particularly in the treatment of spirit and drug neurotics, is due to the want of persistence and careful study by men who undertake this work. There are so many difficulties and complexities of causes, with equally changing results, as to tax the highest therapeutic skill of the physician.

One fact seems to be well substantiated by all experience, that a large proportion of these neurotics require institutional treatment at first, and then personal care by the family physician, extending over a long period of time. In this way permanent restoration can be secured. Institutions ought to be fitted for brief and emphatic treatment for a certain class and long home treatment for others. Such places are in existence to-day, but they ought to be multiplied over and over again.

In my own experience, covering forty years, I have found an increasing number of active brain workers who resort to places of this kind, as to cities of refuge, where they can receive rest, quiet, and medical treatment for a brief time, much the same as persons go to the mountains and seashore, expecting by the change to recover from their disability and weariness.

Sanatoriums in the mountains and in attractive surroundings find the number of steady visitors increasing year after year. They come for a longer or shorter stay to receive new vigor and strength.

A certain number of persons who are practically inebriates are able to divert the drink obsession by coming to institutions and being cared for and treated for a short time. Such persons anticipate by distinct auras the oncoming drink craze and in this way are able to avert it and continue lives of abstinence.

What I plead for, are more places of this class, more places of refuge, where psychical as well as physical treatment can be given, and where active men and women can recover and be fitted to resume the active duties of life. There is a new army of invalids gathering in this direction which the wise physician can do much to help, but this must be along different lines from those laid down in conventional text-books.

Medicolegal Notes.

Duty as to Removal of Pads.—The Kentucky Court of Appeals holds that, in performing an operation, it is the duty of a surgeon to exercise reasonable care and skill throughout, from the time the incision is made until the opening has been closed in the proper way, and to remove the sponges or pads necessary to a successful operation. The removal of the sponges, the court said, is a part of the operation, and an operation cannot be said to be concluded until such removal takes place. For this reason, it is generally held that a surgeon cannot relieve himself from liability for injury to a patient by leaving the sponge in the wound after the operation, by any custom or rule requiring the attending nurse to count the sponges used and removed, accompanied by the statement of the nurse that the sponges were all properly accounted for, and his reliance on such statements. On the contrary, surgeons are generally held liable for injuries resulting from their leaving a gauze sponge in the abdominal cavity of the patient. But the custom of requiring the attending nurse to count the gauze pads used and removed and the defendant's reliance on the nurse's count were held to be proper circumstances to be considered by the jury, in connection with the other facts attending the operation, in determining whether or not the defendant exercised reasonable skill in the performance of the operation.

Malpractice—Consent to Operation—Reading of Medical Works in Evidence—Expert Evidence.—In an action against a surgeon and an incorporated infirmary where the surgeon operated it was alleged (1) that the defendants wrongfully, intentionally, and without her consent, amputated one of her legs, and (2) that they so negligently and unskillfully treated the leg, which had been accidentally broken, as to make its amputation necessary. The treatment and operation having been prescribed and performed by the surgeon under an independent employment by the plaintiff, it was held that the infirmary corporation was not liable, though the surgeon was one of its shareholders and officers. Although many other courts hold differently the Alabama Supreme Court holds that relevant extracts from medical treatises, recognized and approved by the medical profession as standard, may be read to the jury in evidence. In the present case it was held proper to permit an expert medical witness to be asked on cross-examination whether it was true, as stated in Scudder's Treatment of Fractures, that "It is not very uncommon, even in closed fractures of the femur, to find gangrene of the leg developing because of laceration or pressure upon the great vessels of the limb. Early amputation of the thigh just above the fracture will be necessary in these cases. It should be done early in order to save life." This was a statement of surgical theory and practice, and the gist of the question was whether the witness's expert opinion concurred with that of the author. The defendant surgeon was allowed, after consulting the fever charts that had been kept by the nurses, to state what these charts showed in respect of the patient's temperature. This evidence was held admissible because these references to the temperature charts, read in connection with the rest of the defendant's examination, amounted to nothing more than statements of some of the considerations that influenced his professional judgment from time to time in respect of the proper treatment to be followed. The plaintiff testified that she was ignorant that her leg had been amputated for several days after the operation. A question was asked a nurse as to whether the plaintiff knew her leg had been amputated. It was held that if this question was improper as calling for the witness's cognizance of the state or operation of the plaintiff's mind, it was rendered harmless by her answer that the plaintiff would lie and watch the leg being dressed every time it was dressed, as she stated only cognizable facts. The court refused to conclude, as a matter of law or fact, that an expert medical witness transcended the limits of all possible human attainment when he testified that there was no way known to medical science to prevent thrombosis in a case of this sort, and the doctor was entitled to give his opinion. The plaintiff had been under treatment by an expert physician and surgeon for two months before she came under the defendant's care. Judgment for the defendants was affirmed.—Barfield vs. South Highland Infirmary, Alabama Supreme Court, 68 So. 30.

Liability for Injury from Unsound Oysters Served in Dining Car—Evidence of Experts.—In an action for damages for having been made ill by food (consisting chiefly of eggs and oysters) furnished to him by the defendant railroad company in its dining car, the witnesses whose opinions were admitted by the trial court were expert, some as medical men, others as cooks and persons long accustomed to handling and preparing oysters for the table. The court, on appeal, held this evidence admissible under the rule that a witness may have expert knowledge of some of the ordinary affairs of life. By competent expert opinion of attending physicians the plaintiff sought to show that his illness was the result of ptomaine poison, and, by a process of exclusion, that the putrefactive bacteria producing the poison found their way into his stomach by means of the food served to him on the defendant's dining car. If the evidence to this effect was to be believed the plaintiff's case thus far was quite well established. This put upon the defendant the burden of showing that its servants, in the selection and preparation of the food, had exercised that degree of care which a reasonably prudent person would exercise in the selection and preparation of food for his own table. In this connection it was for the jury to consider, so far as concerned the oysters, the nature of sea foods and their commonly known capacity for rapid deterioration in certain conditions. It is possible that the highest degree of care consistent with the use of such articles as food may not suffice to detect the small beginning of a putrescent decay which by rapid development in the conditions provided by the human stomach may result in disastrous consequences. This the plaintiff must be presumed to have known as well as the servants of the railroad company, and this general risk he took when he chose oysters for his food. But it was for the defendant to show that its servants exercised the proper care in this case, and that such care failed to disclose any reason for suspecting the quality of the food. Whether there was negligence in selecting the particular oysters served to the plaintiff was held to be a question of fact for the jury.—Louisville & N. R. Co. vs. Travis, Alabama Supreme Court, 68 So. 342.

MEDICAL RECORD.

INDUSTRIAL LEAD POISONING.

IN Great Britain and in some parts of Europe the question of poisoning by metallic and other chemical substances has received the attention which its manifest importance deserves. It is recognized that much of the sickness due to industrial poisoning is preventable, and the health of the employees in factories in which poisons dangerous to well being are used is safeguarded by various devices. The employer is rendered responsible, to a great extent, for the health of those working for him, that is, the law enforces regulations calculated to prevent the occurrence of sickness from poisons employed in the manufacture of some articles of commerce, and if the employer does not live up to these regulations he is liable to fines varying in amount proportionate to the danger incurred.

In this country, the matter of industrial poisoning has been greatly neglected, and indeed the enforcing of regulations is not easy. As Dr. Maria M. Vinton points out in the *Woman's Medical Journal* for October, 1915, the difficulty in the problem of prevention in those industries in which lead is used is because the employees, being ignorant and frequently not understanding English, are not aware that the dust they are inhaling is poisonous, and could not read and comprehend warnings even if posted, while the foremen and employers do not always take the precaution to warn those ignorant ones of their danger. The most common form of metallic poisoning is with lead, since there are 125 or more trades in which this substance is used in some way which makes it dangerous to the operative. Besides poisoning from lead, there occurs poisoning from arsenic, antimony, chromic acid, phosphorus, mercury, hydrofluoric acid, and naphtha.

In the Bulletin of the Bureau of Labor, No. 95, Dr. Alice Hamilton gives a most valuable account of the white lead industry, which is responsible for the largest amount of lead poisoning, and which she investigated for the United States Government. She describes at length all the processes of manufacture of white lead, the causes which produce the dangerous dust, and the improvements that can be made in the process of manufacture, such as have already been put into use in Great Britain and in certain parts of Europe.

Dr. Vinton recounts in detail the manner in which lead enters into the system and the various forms of lead poisoning, as well as the treatment thereof. Prevention, however, is always better than cure, and she points out that the prevention of lead poisoning, as of all metallic poisoning, lies in better ventilation of the works where it is handled, by means of exhaust fans which remove the dust-laden air, the changing of the process of production so that there shall be as little dust as possible, and the use of sprinklers in all dusty processes, the building of factories with hard, smooth floors, and insistence on the point that there shall be no outstanding places on which dust can lodge. In fact, every sanitary measure calculated to minimize the menace of lead poisoning should be adopted in every factory in which the substance is used. Furthermore, an important point in the prevention of paint lead poisoning is the use of a substitute for lead. In paint for inside use the substitution of non-poisonous zinc white or zinc oxide for white lead has been adopted in Europe, and zinc has been found as good as lead for all interior decorations. Lead sulphate, being insoluble, is also not dangerous.

Among printers, one of the principal elements in lead poisoning is the dark, unsanitary places in which the men often work, which predispose them to tuberculosis; and plenty of light and sunshine in the workrooms and the enforcement of sanitary precautions would go far to prevent this disease, so prevalent among printers and typesetters.

There is no doubt that laws and regulations to protect industrial workers in this country are not as strict as they might be, and it is a matter to which the attention of the public should be called. If public opinion is thoroughly aroused to the menace to life and health involved in neglecting precautions which will protect and prevent, the lot of the industrial workers will be greatly improved and the health of the community at large will be measurably increased.

POOR ECONOMY.

THE conversion of the Sea View Hospital into a department of the Poor Farm of Greater New York, has been practically accomplished without consultation, so far as we know, with any authority on tuberculosis. The sole reason given for the consolidation is that the measure is one of economy. It is not the function of a medical journal to scrutinize the latter, but we may note that in Dr. Baruch's protest before the Board of Estimate it was shown that the consolidation, so far from promoting economy, will involve an increase of several thousand dollars over the cost of maintenance of both institutions in their present separate condition. Even if a saving were demonstrated, it would be false economy to place the Sea View Hospital, having perhaps the finest buildings devoted to tuberculosis in the world and now directed by a man who has made this disease a practical study for many years, under the direction of a layman and place it under the medical control of a physician whose duty it is to attend the senile derelicts who constitute the inmates of the Poor Farm (the Almshouse) of this city. That all research work or therapeutic obser-

vations now going on will sooner or later cease under such management is self-evident to any one who has had experience. In fact, this consolidation is in direct contravention of the recognized practice of no longer treating epileptics, the insane, and tuberculous patients in the poorhouses. This is not only the general practice but is actually the law in this State, effective in all counties except New York. The character of an Almshouse differs so materially from that of a tuberculosis hospital that the principle of separation is fundamental and has the entire weight of medical opinion to sustain it. Shall a hospital costing $4,000,000 become part of an almshouse and shall we thus return to the old and abandoned practice of placing the tuberculous under the same management as the senile poor; in other words, place under the same direction the latter, who are not accepted unless able to walk and above 55 years old, and the former who are all sick?

At the present time the poor are well looked after on the poor farm, and the tuberculosis cases in the Sea View Hospital are under the skillful care of a specialist with a large visiting and consulting staff that costs the city nothing. The present medical superintendent gives personal attention to the wards, supervising diet, etc. Under the new combination the poorhouse doctor will be assisted by young men whom he will naturally not be able to direct in the tuberculosis work as skillfully as the specialist. The type of physician who would accept the Almshouse position with the salary proposed may be competent to look after the ailments of the senile, but it is improbable that he would be capable of attending to the 700 actually sick now in the Sea View Hospital and the 1,000 incipient tuberculosis cases which it is proposed to harbor in the contemplated new hospital for incipient cases. It would be far wiser to have the superintendent of the Sea View Hospital direct the Almshouse doctor whose patients will be very few in comparison, and to appoint a lay manager for both without authority to interfere in the medical department.

When the incipient tuberculosis hospital is completed this city will have an institution in which the best research work in pathology and therapeutics will be possible, the result of which must surely redound to the credit of the medical profession and to the great benefit of suffering humanity. But this will be only if the hospital is under expert management. A political or even a civil service appointee who has only the qualifications necessary for a poorhouse doctor can hardly be expected to utilize to the best advantage of science or of the patients the facilities for study and research which this great hospital will offer.

THE RESISTANCE OF ACID-FAST BACILLI TO ANTIFORMIN.

SINCE the publication of Uhlenhuth's first work on antiformin in 1908 this compound has been used very largely as an aid in the search for tubercle bacilli in secretions and excretions. From the beginning there was no question but that it exerted a rapidly destructive action upon all except the acid-fast organisms, but its action upon the latter group has been the subject of a certain amount of discussion. The earlier investigators claimed that all of the members of this group of bacteria were resistant to the action of the solvent, and that therefore it could not be relied upon to identify the tubercle bacillus in the presence of such organisms as the smegma bacillus. Then acid-fast bacilli were discovered to be present in the distilled water of laboratories and in the water used to make the antiformin solutions, and at one time the method was near to being discarded completely. Later researches yielded results that were contradictory, and several authors make the statement that the smegma bacillus is destroyed by antiformin and that only the tubercle bacillus is able to survive its action.

Von Spindler-Engelsen is the most recent contributor to this subject (*Centralbl. f. Bakt.*, 1915, lxxvi, 356). She readily confirmed the results of other writers by finding that the staphylococcus and the *Bacillus mesentericus* were completely dissolved by 12.5 per cent. antiformin in thirty minutes. The smegma, hay, and butter bacilli were dissolved by 15 per cent. antiformin in one-half hour, while the *B. tuberculosis anguis* yielded only to 50 per cent. after twenty-four hours. The human and bovine types of the tubercle bacillus remained apparently unaffected after treatment with 50 per cent. antiformin for four days. The conflict of results is perhaps not so difficult to explain if one recognizes how readily antiformin loses its strength on standing. It is probable that this author used a fresh preparation of high potency while some of the other writers were working with older and weaker solutions. It is to be hoped that such will prove to be the case for the method is undoubtedly of great value. In the examination of urine, feces, and fluids from the pleural cavity it may yield results in much less time than is necessary for animal inoculation, and with the more recent modifications in technique the percentage of positive findings is much higher. The use of antiformin, treated material for cultural examination after the method of Petroff is perhaps even better, when the opportunity affords, since the cultural characteristics of the organism are fairly definite and the time required is less than for animal inoculation.

LACTIC ACID TREATMENT OF TUBERCULOSIS.

A NEW application of chemotherapy in the treatment of pulmonary tuberculosis is reported by F. Jessen of the Forest Sanatorium of Davos (*Zeitschrift für Tuberkulose*, July, 1915). This new method was suggested by the use of partial antigens in the treatment of tuberculosis, which antigens were obtained from tubercle bacilli by subjecting the latter to the action of dilute acids. It was found that weak solutions of lactic acid readily destroy tubercle bacilli growing in culture. The question arose whether this action might not also be exerted in the living body. Accordingly Jessen essayed the use of intravenous injections of one per cent. solutions of lactic acid in the treatment of incipient cases of pulmonary tuberculosis. The results are said to have been brilliant. The amount

of the solution injected at one time is not mentioned though the statement is made that the injections were used from once a month to once or twice weekly, according to the severity of the case. The point is emphasized that this method of treatment is suitable only for early cases of the disease. In advanced cases a considerable part of the tuberculous area is not reached by any medication introduced into the blood stream. Moreover if the disease is extensive the lytic action of the lactic acid may be so great as to overwhelm the body with the toxic decomposition products of the tubercle bacilli.

Blood as Food

Generally speaking, blood through its protein constituents has considerable food value; some parts of it are much better adapted for food purposes than others; some parts of blood may disagree and do not seem to be adapted for food. Here belong the erythrocytes, the nitrogen of which is poorly utilizable. Fibrin, on the other hand, is as utilizable as any other albumin. At a session of the Medical Society of Frankfort last May (*Berliner klinische Wochenschrift*, July 5) Blum reported the results of feeding certain animals with blood. Rats all took it greedily, as did most of the dogs fed. Cats practically refused it, but could be made to eat it. When fed on red corpuscles alone rats developed a fatal diarrhea. Blood pudding or sausage has been known to cause urticaria in human beings. In regard to utilization this is very poor for red corpuscles, not very good for whole blood and defibrinated blood, but excellent for blood fibrin and serum albumin. In discussion von Noorden stated that blood is not well absorbed, and that raw blood is laxative. Cooked blood is much better, but after the absorption of five grams of blood nitrogen each additional fraction is absorbed with increasing difficulty; so that it does not pay to consume it in considerable quantities, and the extra nitrogen should come from other sources. Blood pudding, von Noorden said, is an excellent dietetic article.

News of the Week.

Harvard Surgeons for Work in France.—The second Harvard hospital unit, consisting of thirty surgeons and thirty-six nurses, sailed from New York, on Wednesday of this week on the steamship *Noordam* for service in the war zone. Dr. David Cheever of the Harvard Medical School was in charge of the party.

An American Physician a Russian General.—Dr. Philip Newton of Washington, has been appointed surgeon of the Russian Sixth Army Corps, with the rank of general. Dr. Newton went to Russia in charge of a Red Cross unit.

Misuse of Hospital Ships Denied.—The British Admiralty issued a statement last Sunday, saying: "In a German wireless message sent out on the night of November 12 it was conjectured that British hospital ships are being used for conveying troops, munitions, and other war material. This is absolutely false. British hospital ships always have and always will be used under the conditions prescribed by the Geneva and the Hague Conventions."

American Doctors Prisoners in Serbia.—When the Bulgars recently captured Uskub from the Serbians they made prisoners of Lady Ralph Paget and most of the members of the staff of her hospital. Among those who elected to remain with Lady Paget were Dr. Catherine Travis of Canada and the following American doctors: S. H. Osborne, C. E. Fox, F. E. Cornelius, B. A. Ohr, and Harry Plotz, and five Columbia University men, Elmer Childs, Douglas Dold, Elliot Dold, Arnold Bell, and Mr. Little.

Help for the War's Disfigured.—The American Red Cross, cooperating with a number of influential Americans, has formed a nation-wide organization to raise funds for a hospital in Paris for the treatment of facial wounds. At present there is no place where soldiers who have suffered disfiguring wounds can be treated. The new hospital will be devoted to skin grafting and other work necessary in the rebuilding of parts of the human body.

Civil Service Examinations.—The United States Civil Service Commission announces an open competitive examination for assistant in metabolism investigations, male, at a salary of $1,500 a year. From the register of eligibles resulting from this examination certification will be made to fill vacancies in the United States Public Heath Service in the field, and vacancies as they may occur in positions requiring similar qualifications. Applicants for the examination must be citizens of the United States, less than forty-five years of age, and graduates from a four years' course at a college, university, or medical school of recognized standing, with at least six months' practical experience in work with the respiration apparatus and calorimeter. Persons who meet the requirements and desire to take the examination should apply at once for Form 1312, stating the title of the examination, to the United States Civil Service Commission, Washington, D. C.

The Civil Service Commission of New York State will hold examinations in various cities throughout the State on December 11, 1915, for the purpose of filling the following vacancies:

Woman physician, State hospitals and institutions, $1,000 to $1,500 and maintenance. Candidates must be licensed medical practitioners of the State of New York and must have had at least one year's experience on the medical staff of a hospital or three years' experience in the general practice of medicine. Candidates desired in both regular and Homeopathic schools of medicine.

Research assistant, Kings Park State Hospital, open to men and women, $600 and maintenance. Candidates must have had a full collegiate education with subsequent experience in psychological and biological research, especially in connection with human heredity.

Physician, to attend persons sustaining injury due to work under compressed air, Public Service Commission, First District, $2,250.

Assistant in radio-physics, State Institute for the study of Malignant Disease, Buffalo, N. Y., $1,200.

Applicants for the examinations must be citizens of the United States. Application blanks and special bulletins of information regarding the positions may be obtained from the State Civil Service Commission, Albany, N. Y., before November 29.

Montefiore Home.—The annual meeting of the contributors to the Montefiore Home and Hospital for Chronic Invalids, New York, was held at the home on November 7, when addresses were made by Dr. Abraham Jacobi and Commissioner of Charities Kingsbury. The report of the treasurer

showed that during the past year the contributions totaled $336,000, while the total expenditures were $340,000.

Red Cross Endowment Fund.—An endowment fund of one hundred thousand dollars, a membership comprising every man, woman, and child in the United States, and a merger under its banner of all the war relief societies—these are the aims of the American Red Cross as announced at a meeting in New York on November 9. Ex-President William H. Taft, recently appointed chairman of the Central Committee of the Red Cross, was among the speakers.

For Disease Prevention.—The American Museum of Safety has received a gift of money which will make possible the carrying on of a campaign for the purpose of minimizing disease among the workers in the shops and factories of New York City.

Price of Radium Reduced.—The Director of the United States Bureau of Mines recently announced that the cost of radium had been reduced from $120,000 to $36,000 a gram, through the work of the research bureau. The bureau has been engaged on the problem of the cheaper production of radium for the past year.

Death Rate in Chicago.—The number of deaths reported in Chicago during the week ending October 30, was 581, giving a rate per annum of 12.4, while for the corresponding week of last year the number was 519, and the rate 11.3. The largest increase was in the age group between 60 and 70 years.

During the week ending November 6, the number of deaths in Chicago was 595, as compared with 528 for the same week of last year. The death rate for this week of 1914, computed on an estimated population of 2,393,325 was 11.5 per thousand, while for 1915 the rate, computed on an estimated population of 2,447,045, had risen to 12.7.

New York Death Rates.—During the week ending October 30 there were in New York City 1,194 deaths, a death rate of 10.73 per thousand, while in the same week of last year there were 1,134 deaths, a death rate of 10.60, an increase of 60 deaths and of 0.13 in the rate. The death rate from January 1 to date was 13.18 per thousand of population, as compared with a rate of 13.59 during the corresponding period of 1914, a decrease of 0.41.

The death rate in New York, for the week ending November 6, 10.96 per thousand of population, the total number of deaths being 1,220, as compared with a rate of 11.55 for the same week of last year, when the total number was 1,236. It is pointed out by the Health Department that had the rate of last year held for this, the total number of deaths would have been 1,286, so that the decrease in reality amounted to a saving of 66 lives. The death rate for the first forty-five weeks of the year was 13.13 per thousand, as compared with 13.53 for the same period of last year.

Examinations for Sick Leave.—The New York Department of Health will hereafter examine all city employees who make application for protracted sick leave. This supervision will cover about 10,000 municipal workers, although the members of the police, fire, and street cleaning departments, will not be included, as they already have physicians to perform such inspections.

Nobel Prizes.—Announcement has recently been made of the award of the Nobel prize in chemistry for 1914 to Prof. Theodore William Richards of Harvard University, for his work in fixing the atomic weights of chemical elements, and of the prize in physics for the same year to Prof. Max von Laue of Frankfort, for his discovery of the diffraction of rays in crystals. The prize in medicine for 1914 has been awarded to Dr. Robert Barany, of the University of Vienna, who has made important investigations in the physiology and pathology of the ear.

Bequests to Charities.—The Hospital for Consumptive Children under the will of the late Mrs. Mary M. Johnson of this city receives, subject to the life interest of relatives, a half share in a fund of $106,938.

Columbia University has received from the executors of the estate of Mr. William D. Sloane the sum of $50,000 to be added to the endowment fund of the Sloane Hospital for Women.

By the will of the late Dr. De Benneville K. Ludwig of Philadelphia 10 per cent. of his residuary estate is bequeathed to the Presbyterian Hospital.

By the will of the late Jane H. Harmer of Philadelphia the sum of $5,000 is bequeathed to the Germantown Hospital for the endowment of a free bed in memory of her husband, George Wilson Harmer, and her son, Harry G. Hale Harmer; $5,000 to the Allegheny General Hospital at Pittsburgh, for the endowment of a free bed in honor of her father and mother, Henry G. Hale and Elizabeth Hale, and $2,500 to the Children's Hospital of Pittsburgh for the endowment of a free bed in memory of her sister, Elizabeth Hale Phillips, and her son, Hale Phillips.

The Long Island College Hospital, Brooklyn, has received $75,000, the House of St. Giles the Cripple, Brooklyn, $30,000, the Providence Hospital, Washington, $15,000, and the Hudson City Hospital, Hudson, N. Y., $25,000 under the will of the late Mrs. Katherine S. Leavitt, who died in Washington in September, 1914.

Sterilization of Feeble-Minded.—Operations for sterilization, the first under the new Wisconsin law, were performed recently on ten male inmates whose ages ranged from fifteen to thirty years at the Wisconsin State Home for the Feeble-Minded, Chippewa Falls.

Hygienic Servants Demanded.—As an outgrowth of the plan of standardizing household help in Montclair, N. J., the Montclair health department has announced that for a fee of three dollars it will examine the physical condition of applicants, and when the result is satisfactory will issue certificates of health. Blood tests and examinations for tuberculosis, etc., will be included in the examination. At present the barbers and those engaged in handling food supplies in Montclair are required to pass such an examination. The plan has been endorsed by the Housewives League.

Open Cars in Brooklyn.—The Brooklyn Rapid Transit Company announces that during the coming winter it will run open cars on the surface lines for the convenience of smokers and those desiring fresh air.

Opposed to Sales of Narcotics.—The American Association for the Study and Prevention of Infant Mortality at the sixth annual convention, held in Philadelphia on November 12, adopted a resolution refusing to endorse any law whose effect would be to continue the sale of narcotics in any medicine. The attempt in many States to regulate by legisla-

tion the traffic in narcotics and habit-forming drugs has not been successful, in that there has been exempted preparations containing but a small quantity of such drugs.

Manhattan Census.—The Police Department of New York, at the request of the Department of Health, recently undertook a test census of the Borough of Manhattan, as a result of which the population of the borough is placed at 2,295,671, or 192,465 more than was estimated by the State Census Bureau, which also took a census last spring. As a result of its estimation the State Bureau has contended that the computation of the death rate of the city by the health officials was too low, the falling off in immigration and the increase in emigration on account of the war having somewhat checked the normal growth of the city's population. The Health Department, however, has questioned the accuracy of the State's figures, and the police census upholds its claim and indicates that its estimated death rate of 13.13 per thousand for the first forty-five weeks of this year is correct.

Christian Scientists Convicted.—Two women practitioners of Christian Science in Berlin are reported to have been convicted of criminal carelessness and sentenced to six months' imprisonment for causing the deaths of two actresses in the Royal Theater. Although both of the patients were said to have been suffering from serious and perhaps incurable diseases, it was thought that their lives might under customary treatment have been much prolonged, and for this reason the court found the defendants guilty.

City Baths.—In Manhattan Borough during the past summer the total number of baths taken in the public pools was 1,324,341, or 230,000 more than during the summer of 1914. The cost of each bath was less than a cent and a half.

Goat Milk in Tuberculosis.—A herd of thirty-six goats from the United States Department of Agriculture was received on November 12 at the Sea View Sanitarium, Staten Island, where the experiment of giving the milk of these animals to tuberculous patients is to be tried.

Personals.—Dr. RICHARD MILLS PEARCE, professor of research medicine at the University of Pennsylvania, recently received the degree of doctor of science from Lafayette College.

Dr. ROBERT H. MULLIN, director of the laboratories of the Minnesota State Board of Health, will shortly take charge of hygienic laboratories of the University of Nevada.

Dr. H. G. EARLE has been appointed professor of physiology at the University of Hong Kong.

Medical College Merger.—Arrangements have recently been completed by which the Medico-Chirurgical College of Philadelphia will be merged with the University of Pennsylvania, a step which has been under contemplation for some time. The Medico-Chi will become a graduate school of the university, and the latter will have control of the former's endowment.

The Late Dr. Huddleston.—At the regular meeting of the Willard Parker and Riverside Hospitals, held at the Willard Parker Hospital, on November 9, 1915, it was unanimously

Resolved, That the Medical Board has learned with profound regret of the untimely death on October 30, 1915, of its President, Doctor John H. Huddleston. By his death the Board has been deprived of an ideal presiding officer—a man of judicial temperament, pleasing personality, and broad knowledge of the great work in which these Hospitals are engaged.

Resolved, That the Medical Board feels that the death of Doctor John H. Huddleston is a great loss to modern medical science and sanitation. Not only was he possessed of exceptional attainments but he unselfishly devoted his energies, time, and interest to the furtherance of all practical measures for the advancement of the public good in these fields.

Resolved, That the members of the Medical Board mourn the loss in his death of a dear colleague, ever kind and courteous and sincerely attached to all of them, not only officially but by close ties of personal friendship.

Resolved, That we offer to the family of Doctor Huddleston our deep sympathy and condolence in their affliction and express the hope that they will find some comfort in the consciousness of the profound respect and sincere esteem which Doctor Huddleston inspired in his colleagues and in the remembrance of his great usefulness to his fellow men in the important activities which he so well and so thoroughly performed; and furthermore be it

Resolved, That these Resolutions be spread upon the Minutes of this meeting and that copies be transmitted to the family of the deceased and to the medical press of this city.

For the Medical Board,
DR. JOHN W. BRANNAN,
DR. HENRY W. BERG.

Obituary Notes.—Dr. GRACE WOLCOTT of Boston, Mass., a graduate of the Woman's Medical College of Pennsylvania, Philadelphia, in 1884, one of the founders and physicians in charge of the Vincent Memorial Hospital, and a member of the American Medical Association, the Massachusetts Medical Society, and the District Medical Society, died at her home in Heath, on November 9, aged 57 years.

Dr. GERTRUDE GOODING of Bristol, R. I., a graduate of the Boston University School of Medicine, Boston, in 1884, died at her home after a long illness, on October 24, aged 60 years.

Dr. RAYMOND RUSS of San Francisco, Cal., a graduate of the University of California, Medical Department, in 1900, and a member of the American Medical Association, the Medical Society of the State of California, and the San Francisco County Medical Society, died at his home after a long illness, on October 23, aged 42 years.

Dr. FREDERICK GILLETT BYLES of Denver, Col., a graduate of the Jefferson Medical College, Philadelphia, in 1882, professor of hygiene at the University of Colorado, School of Medicine, and a member of the Physicians and Surgeons Club, died at his home after a short illness, on October 22, aged 62 years.

Dr. EDMUND C. RIVERS of Denver, Col., a graduate of the University of Maryland, School of Medicine, Baltimore, in 1879, and a member of the American Ophthalmological Society and the American Otological Society, was drowned in Barr Lake while on a duck-hunting trip, on October 24, aged 57 years.

Dr. ISAAC L. FIREBAUGH of Robinson, Ill., a graduate of the Miami Medical College, Cincinnati, Ohio, in 1875, and a member of the American Medical Association, the Illinois State Medical Society, and the Crawford County Medical Society, died at his home, following an operation, on October 26, aged 67 years.

Dr. EDWARD PORTER COLBY of Boston, Mass., a graduate of the Long Island College Hospital, Brooklyn, in 1861, professor of nervous diseases in the Boston University School of Medicine, consult-

ing neurologist to the Massachusetts Homeopathic Hospital, the Westboro Insane Hospital, and the Whidden Memorial Hospital, and a member of the Massachusetts Surgical and Gynecological Society, died at his home on November 1, aged 76 years.

Dr. GEORGE WHITEFIELD HILTON of Lowell, Mass., a graduate of the Hahnemann Medical College and Hospital, Chicago, in 1877, died at his home on October 27, aged 76 years.

Dr. ALFRED H. MCCORMACK of Northampton, Mass., a graduate of the Trinity Medical College, Toronto, in 1900, and a member of the Massachusetts Medical Society and the Hampshire District Medical Society, died at his home after a short illness, on October 29, aged 43 years.

Dr. GEORGE M. HITE of Nashville, Tenn., a graduate of the Eclectic Medical College, Cincinnati, Ohio, in 1885, died on October 21 after a short illness, aged 57 years.

Obituary.

EDWARD LIVINGSTON TRUDEAU, M.D., LL.D.

SARANAC LAKE, N. Y.

Dr. EDWARD LIVINGSTON TRUDEAU died at his home in the town which he had made famous on November 15, in the sixty-eighth year of his age. In his death, after a long battle against disease, a fight which brought hope and health to thousands of other sufferers from tuberculosis, the world has suffered a loss, and the community in which he was revered an almost irreparable one, though the spirit which emanated from his frail body will live to carry on his work.

Dr. Trudeau was born in New York City on October 5, 1848, the son of a physician, Dr. James Trudeau of this city, and was graduated from the College of Physicians and Surgeons, New York, in 1871. He began practice in New York in 1872, but two years later he was stricken with tuberculosis and was told that he had but six months to live. Going to the mountains with the hope only of passing a few months more comfortably, he found that the open-air life in the high altitude was of benefit, and lived to found an institution which has become one of the great sanatoria and to see his theories as to the proper treatment of tuberculosis widely accepted. In 1885 the first shack of the Adirondack Cottage Sanatorium was opened, and from this small beginning there has grown a beautifully planned institution, housing more than one hundred patients and devoted to the treatment of the working men and women of America. With his clinical work Dr. Trudeau also carried on scientific investigations, and the burning, through the explosion of a lamp, of his small laboratory many years ago, was the occasion of the widely-quoted message from Dr. William Osler. "Dear Trudeau: I am sorry to hear of your misfortune, but take my word for it there is nothing like a fire to make a man do a Phoenix trick." In 1894 Dr. Trudeau was able to establish the Saranac Lake Laboratory for the Study of Tuberculosis, the first research laboratory for the purpose in this country, which is now adequately housed in a brick building near his home. He had written extensively on the subject of tuberculosis, and was a member of the American Medical Association, the New York State and Franklin County Medical Societies, the Association of American Physicians, and the National Society for the Prevention of Tuberculosis.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

LOCAL GOVERNMENT BOARD—EXCESSIVE MATERNAL AND INFANTILE MORTALITY—ROYAL SOCIETY OF MEDICINE, FRACTURES—MEDICAL SOCIETY OF LONDON, SCIENCE AND WAR—PARATYPHOID IN THE EXPEDITIONARY FORCE—TYPHUS IN SERBIA—WAR STRAIN.

LONDON, Oct. 30, 1915.

THE report of the Local Government Board just out contains the medical officer's statement as to the excessive mortality, both maternal and infantile, in connection with childbearing in different localities, and it is hoped the facts will stimulate local inquiry and encourage measures of prevention. As is shown in a table, there has been a remarkable decline in the national death-rate, but another also in the birth-rate, the total result being a fall in the rate of increase of the population. The balance between emigration and immigration for the last ten years, compared with the previous equal period, involves a similar decrease. The death-rate can still be much reduced. A great proportion of deaths under 70 are really unnecessary deaths. Of the total mortality, 44 per cent. of deaths occur under 40 and 76 per cent. under 70 years of age. But the fall in death-rate cannot indefinitely keep pace with a continuous fall in birth-rate. The average age of the national population is already on the increase, and by consequence its proneness to death. The figures emphasize the importance of preventing further decrease of the balance of births over deaths by such measures as tend to preserve the lives and maintain and improve the health of mothers and their children.

To this end public rather than private action is being advocated by many—by some indeed who have heretofore been content to regard it as "a doctors' affair" but who now say the responsibility falls on the local authorities. As their record is not very encouraging there is a demand for an act of Parliament to compel them to perform their duties efficiently, and if necessary to provide grants toward the cost involved. Here is a chance for the local government board to do something; its president, Mr. Walter Long, at the Guildhall on Tuesday made a stirring speech with special reference to infantile mortality. It was at a large, representative meeting to promote the campaign of the national association for the prevention of this excessive mortality. Cabinet ministers, bishops, noblemen, and others interested were present. Mr. Long held that there is ten times more need for the movement since the outbreak of war. Letters were received from the Queen and from Queen Alexandra. Mr. Long, as president of the local board, assured the meeting of the sympathy of that body. Sympathy is good as a preface to action.

The mortality connected with parturition from conditions other than puerperal fever, as to which there is a general uniformity, is much lower in London than in the provinces, to the extent that more than 800 mothers would be saved in a year if the statistics in the country were equal with those of the metropolis. But in puerperal fever London shows no better figures than the country. If this disease were eliminated as it has practically been in many lying-in hospitals, there would be a further saving of 1100 mothers' lives. Welsh counties have

the highest maternal mortality, some agricultural counties as low or even lower than London. Manchester, Liverpool, and other large cities hold a relatively favorable contrast to many Lancashire and Yorkshire towns. Scotland, Wales, and Ireland have a higher child-bearing mortality than England. A study of the incidence in different localities, especially of the extreme variations, shows that special local factors must be concerned. As to causation a close relationship between factory work for married woman is indicated and the medical officer says the presumption is justified that better ante-natal and midwifery care would go far to reduce maternal mortality. It is said measures should be taken by ante-natal consultations, clinics, visiting, etc., to ascertain and help the cases needing assistance.

At the Royal Society of Medicine we have had an exhibition of fracture apparatus. Sir A. Keogh, who opened it, remarked on the use of such displays in diffusing information and the difficulties of spreading knowledge in such a way as to contribute to uniformity of practice. He commended the French methods of splinting and said much of the technique adopted in the exigencies of war would remain in civil practice. Sir Almroth Wright then gave an address on the employment of bandages for the irrigation of wound-surfaces with therapeutic solutions and the draining of wounds. This he held has the advantage over wet dressings that we can bring our solution continuously into application without altering the concentration—a point of fundamental importance with saline remedies. We can, moreover, with proper arrangements, apply our agents to all internal and external surfaces of wounds while at the same time securing ideally effective drainage. He then described the various arrangements which he thought would satisfy all requirements.

The various methods of splintering fractured limbs naturally took the most prominent place in the exhibition and surgeons who were engaged in such work expressed surprise at the ingenuity shown in many of the appliances submitted to their notice.

At the Medical Society of London, Dr. W. Pasteur, president, delivered the opening address of the session. He referred to the smallness of the last volume of their proceedings which was due, he said, to the war, for that interfered with attendance at their meetings, one-third of their members being on active service either at home or abroad. But the war greatly increased material for investigation and our command of the sea allowed the wounded and sick to be brought home. In spite of the horrors of the war it would add greatly to our medical knowledge. But there was much difficulty in making use of the material available. Taking notes in periods of rush was not easy and the patients were often wafted away before their cases had been completely investigated. Two groups of cases under his own observation were (a) pulmonary tuberculosis and (b) enteric. As to the former in soldiers invalided from the service hemoptysis was prominent and in the majority there was a history of previous pleurisy or lung affection, but the physical signs were indefinite and rapid improvement followed removal to favorable conditions. The enteric group was of great interest and included typhoid, paratyphoid, dysentery, trench diarrhea, and intestinal protozoal diseases. Most came from the Near East, were benign, and generally recovered. In modified typhoid the onset was sudden, pulse low, headache slight, enteric symptoms indefinite or sometimes even wanting, spots uncommon or difficult to distinguish, spleen not often enlarged. The temperature often fell to subnormal a few days before convalescence set in. Of course whether inoculation has been performed is to be considered. It is an open question whether trench diarrhea represents relapses. The suppression of the abdominal symptoms is the chief characteristic of the modified disease.

In connection with the foregoing I may refer to an interesting account of the characteristics of paratyphoid by Captain Henry Robinson, based on 89 patients admitted as enteric suspects from the British Expeditionary Force in 47 per cent. of which a paratyphoid bacillus was isolated. Although marked differences were observed among these cases they are with two or three possible exceptions manifestations of a definite clinical entity. Dr. Robinson concludes from a careful study of the cases that paratyphoid as seen in the British force, is much milder and shorter than typhoid, its onset either gradual or moderately sudden, headache and abdominal pain the most constant symptoms, next to them shivering at onset, cough, pains in limbs and back, diarrhea or constipation, nose-bleeding; all these are met with in from 30 to 60 per cent. of cases. Vomiting at onset followed by sore throat is not rare, definite rose spots in about 60 per cent., abdominal reflex absent in nearly 50 per cent. Brief relapses not uncommon. Complications are more rare and are counterparts of those met in typhoid. The paratyphoid bacillus (A or B) may often be isolated from the feces but in many cases only after subsidence has begun. But one negative finding is not conclusive. Widal reactions may help those experienced in their application if read in conjunction with clinical evidence and previous history, *e.g.* as to inoculation. The prevention of the spread requires the same precautions as true typhoid. Carriers should be closely watched, for bacilli may be found in their excretions after all symptoms have subsided.

The Chadwick Lectures at the Royal Society of Medicine were delivered by Dr. R. O. Moon on "Typhus in Serbia." In the first lecture, on the 20th inst., he said that during the present war the armies of France and England, fighting in numbers never before equaled remained free from typhus. This great result should be attributed largely to the inspiration of Chadwick, whose arduous labors for public health were perhaps more recognized in France during his lifetime than in his own country.

Dr. Leslie Murray, lecturing at the Institute of Hygiene on "War Strain," said the terrorizing policy of Germany was the direct outcome of the study of the psychology of war. Their object was to destroy the morale of their enemies while raising that of their own people, telling them only about victories. Submarine and Zeppelin attacks were to inspire terror, the results not being measured by military effects nor even by the number of civilians killed. Such atrocities excited disgust rather than fear, though they might aggravate the war strain, especially on the aged and on nervous women and children. To prevent the ill effects of the strain they must do everything to maintain the general health—good food, fresh air, exercise, regular habits, above all, sufficient sleep.

Mortality of Communicable Diseases.—Scarlet fever has a fatality rate of 3.1 per cent.; whooping cough, 6.3 per cent.; measles, 1.8 per cent.; and typhoid fever 16 per cent. in New York State.—*Health News.*

1. Medicine—A Profession or a Trade.—Hugh Cabot says that medicine has always been regarded as one of the learned professions, but the tendency of a profession to degenerate into a trade is always present. If Medicine is to avoid the downfall which has overtaken the Law it will be because we are more conscious of the dangers or more alert to check at the beginning undesirable developments. A profession is an occupation requiring an education in science, and which is pursued for its own sake, and must have as its chief end the advancement of science or the benefit of mankind, pecuniary advantage being always a secondary and subordinate consideration. A trade, on the other hand, is an occupation which is pursued chiefly, though not wholly, for the purpose of acquiring wealth. In estimating the importance of any development in medicine we can best do so by comparing present conditions with those of the past, the changes that have taken place and the effect which they have produced upon the prevailing type of practitioner. Dr. Cabot looks back and pictures the type which was looked upon as the highest twenty years ago and compares it with the best that we are producing to-day, and from it gains the impression that the former men were more in touch with affairs other than medicine and more devoted to the ideals of medicine. He also considers the possibilities of the future in the direction of State medicine and of group medicine, and outlines a system of group medicine which seems to him to offer advantages over State medicine.

2. Late Results of Operations Upon the Joints for Hypertrophic Arthritis.—E. G. Brackett and H. W. Marshall make a summary of nine cases whose ages ranged from twenty-nine to fifty-seven, with an average of thirty-five years. Three were women and six were men. Five of the persons were at work at present, on an average time of three years and three months after operation. Four were fairly comfortable and none was completely helpless. The nine reported cases represent four arthrodeses, one decapitation of the femoral head, three cheilotomies, and one arthrotomy for a loose body. The choice of an operation should be made with great care, dependent upon the amount of destruction, the number of joints involved, the social position of the patient and the kind of work which afterward will be demanded of the joint. Efficiencies of patients may be expected to be increased and the pain relieved by surgery. None of these patients was made worse by surgery, and it accomplishes enough to justify itself in those cases which have become seriously disabled by simply relieving continuous pain, or in quickly stiffening some joints to useful positions, or in prolonging their functions and activity. The nine cases are reported.

6. A Successful Treatment for Acute Infections of the Air-Ways.—Irving Wilson Voorhees says that a cold is more than an annoyance; it is a real danger because it may have as a cause the diplococcus of pneumonia or the bacillus of tuberculosis, masked by the micrococcus catarrhalis. A cold is an acute infectious disease and should never be neglected. Most people recover from an acute rhinitis, or laryngitis, or bronchitis, but who can say that these do not furnish the soil and lay the stratum for many other diseases, both acute and chronic? Perpetual warfare ought to be waged against the universal ignorance of those who cough and sneeze in public places without protecting the face with a handkerchief. The course of acute respiratory diseases can be greatly shortened by direct instillations of aromatic drugs, and, of these, a solution of menthol in oil is most effectual. The procedure is absolutely harmless and is of the highest value in treating the throats of singers.

7. Studies in Speech Disorder—Progressive Muscular Atrophy.—Walter B. Swift cites a case of progressive muscular atrophy with involvement of the muscles of the neck to such an extent as to render some sounds impossible and others indistinct, which was relieved at once, and afterward whenever applied, by giving the throat musculature staunch, firm support by the hand, a special high collar being applied to help out the action of the neck muscles.

8. Vincent's Angina. Adolph G. De Sanctis.

1. Value of the X-Ray in the Diagnosis of Gastrointestinal Disturbances.—Julius Friedenwald and F. H. Baetjer consider the following conditions: Esophageal disturbances; gastric and duodenal ulcers; gastric cancer; gastric dilatation and pyloric obstruction; gastroptosis and enteroptosis; diseases of the gallbladder, and chronic appendicitis; intestinal adhesions and angulations. From their studies of many cases of peptic ulcer, in which *x*-ray examinations were made, they believe they are justified in asserting that the *x*-ray offers most valuable assistance in the diagnosis of various morbid conditions in the stomach. In the early stages of gastric cancer the obstruction is not complete, and it is only by means of the *x*-ray that beginning or partial obstruction can be determined. In the early stages they find active contractions of the stomach with slow elimination of contents. Another very important and significant sign is that a portion of the stomach just within the pylorus on the greater curvature shows a tendency to bulge. The prepyloric bulging is dependent largely upon the duration of the affection. The diagnosis of pyloric stenosis with marked and constant retention of food remains and stagnation is extremely simple; but those cases with a moderate amount of retention, often intermittent, and frequently associated with gastrosuccorrhea chronica, are fraught with great difficulty. From their observations, it seems clear that the *x*-ray is a very valuable aid in the diagnosis of beginning pyloric obstructions, as well as in complete obstructions. It is generally admitted that there is no better means of determining the position of the stomach and bowel than the *x*-ray. It is true that the location of these organs can be obtained by other methods, but the *x*-ray examination is so definite that, whenever possible, it should be employed.

2. **Chronic Intestinal Stasis.**—Anthony Bassler believes that intestinal stasis is a condition seen in varied pictures as so-called cases of the condition present themselves. Stasis is distinctly only a symptom, as cough is a symptom of pulmonary conditions, or edema is a symptom of renal disorders. In chronic intestinal stasis theories of the cause of the condition came out only after methods for its correction were inaugurated; it is plausible to assume that from a surgical standpoint the development of this subject has been unscientifically brought about and often as an apology for the rash mistakes made. The first theory advanced was that of Lane and Jordan, which because of an enthusiasm born of biological ignorance, on the one hand, and readiness for surgical exploitation on the other has brought a grave mortality with few successes. At least the failures have finally brought the over-enthusiast to the point of realizing that human life and health are not solely dependent upon surgical alteration of the direction of the fecal current. The work of this enthusiastic surgeon (Lane) based upon the propagandist's hope of the future reminds us of the unnecessary ovariotomies, nephropexies, indiscriminate appendicectomies, anchoring mobile cecums, and operations for splanchnoptosis that have been performed in times past. The diagnosis of chronic intestinal stasis is made by Lane on the basis of certain clinical phenomena and *x*-ray examination. We know that in these cases the *x*-ray method of examination is fallacious. It has been the experience of the writer within the last year to meet people who have been short-circuited, and who have been benefited thereby for the space of a few months, but who now present the identical symptoms of toxemia they suffered from before they were operated upon, although the connection between the ileum and lower sigmoid or rectum is perfectly at work. The Roentgen-ray method of diagnosing intestinal stasis, in which Jordan has done so much work for Lane, while valuable, is likely to lead to error. To Dr. Bassler intestinal stasis is a medical matter almost entirely. Surgical procedures for conditions that ensue as results or complications may be necessary in individual cases, but never the major surgical procedures of Lane for nonobstructive stasis or toxemia, his form of operation for disease in tissue remote from the abdomen, partial types of resections (such as ileosigmoidostomy) being performed in the absence of marked disease of obstruction. The writer concludes that if we are right in our etiological and diagnostic beliefs that diphtheria bacilli in a sore throat mean diphtheria, typhoid bacilli in stools and general system mean typhoid, tubercle bacilli, tuberculosis, and so on; then it is biologically important on etiological, diagnostic, and therapeutic lines that the intestinal infections should be considered from a similar viewpoint. His researches in the pathogenic types show this to be true, the organism found being in the colon, the pseudodysenteric and true dysenteric forms, the *Aerogenes capsulatus*, *Streptococcus fecalis*, alpha and beta types of parotyphosus, the so-called "slimy bacillus," the proteus, alcaligenes, pyocyaneus, butyricus, entericus, macerans, putrificus, subtilis, and others. It is upon the presence and activity of these organisms that the true cause of intestinal stasis is based, and the time must come when this fact will be generally recognized, even though this kind of work is difficult of quick understanding and application in both diagnosis and treatment.

3. **The Sesamoids of the Flexor Brevis Hallucis; Their Importance.**—Noble Price Barnes says that every excessive pleasurable indulgence wreaks its corresponding retribution of discomfort and distress. Consequently to-day we find expressions of yesterday's intemperate use of the feet in the too frequent and furious terpsichorean festivities, the sequel of the insanely popular hesitations, tangoes, fish walks, angle-worm wiggles, peristaltic waves, and other forms of the dizzy whirl perpetually practised by the devotees of "St. Vitus, that blessed patron of the dance." In these days of constant dancing, hard floors and pavements, high heels and thin shoe soles, the trauma comes on gradually. Sesamoid bones are not uncommonly found in the sole of the foot. Most sesamoids have no particular function. Injury to these bones is the result of direct violence, and the extent of the injury is proportionate to the force of the violence or the length of time of its continuance. Serious conditions have hitherto usually escaped recognition until the pathological changes and corresponding disability make complete removal of the sesamoids justifiable. In recapitulation, however, the author states that the sesamoids of the great metatarsophalangeal articulation are a constant and necessary part of the human anatomy and deserve a name; that they are an intricate part of an important joint, having an articulating surface proportionately greater than the patella; they prevent anterior dislocation of the great toe; they are the pulley of the flexor longus hallucis; they sustain the weight of the body much of the time; they are the pivot of locomotion, and they are the fulcrum of the foot.

1. **The Need of Full-Time Health Officers.** — J. W. Kerr says that the cornerstones on which public health administration rests are wise legislation, adequate appropriation, and efficient health organization; but behind the three must of course lie public sentiment if we are to have enforcement of the measures deemed advisable and make possible their success. Public health organization in the United States has been a plant of slow growth and has been stimulated for the most part by epidemics. The funds provided to carry on public health work have been sufficient for the purpose. There is opportunity for great improvement which may best be brought about by the systematic development of local health organization and the employment of full-time health officers who are properly equipped to undertake the special duties that should be required of them. While local health administration should be the strongest, in reality it is the weakest link in our chain of national defenses for disease prevention. By correlating public health agencies, and requiring them to be performed under the direction of a responsible health authority, the community will benefit, and the health official will have an abundance of work to keep him busy. The employment of full-time officers has been made by several states the keystone of their sanitary policy.

3. **The Intestinal Tract.**—S. J. Mixter says that man's interest in the intestinal tract begins at birth and ends only with death. The surgeon first operated on the

beginning and the end of the intestinal tract, but the peritoneal cavity was supposed to be a dangerous region and few invaded it. Intestinal surgery had its real beginning not more than fifty years ago, and step by step it has advanced, until to-day there is not an inch of the intestinal canal or any of its appendages that has not been attacked. The author reviews the things that have been accomplished and points out that there is still much to be learned. The standard must be raised still higher and surgeons must be trained more thoroughly for their work; graduate schools of surgery, large clinics where men can live and work long enough to acquire some of the art and skill of the master, more operations on lower animals, and greater observation and practice in the after-treatment of surgical cases, all these must be within the reach of the would-be surgeon. Technical skill in the surgeon is important, but of greater importance is surgical judgment.

4. **Chenopodium in the Treatment of Uncinariasis.**—William A. Bishop and O. T. Brosius refer to the investigations of Schneffner and Wervoort and Levy as to the value of chenopodium in comparison with other vermifuges in the treatment of hookworm disease and state that they have had an ideal opportunity for carrying out further researches along these lines in the Santo Tomas Hospital, Panama City, where they have a large number of native West Indian negroes and hookworm is an exceedingly common disease. In order to ascertain approximately the efficiency of chenopodium as a vermifuge in unicanariasis in comparison with thymol, it was decided that as good an indicator as any would be a comparison of the average number of hookworms expelled in the whole stool from equal numbers of unselected and previously untreated cases. The cases in which thymol was given and the first whole stool obtained were 60, and the average number of hookworms expelled was 76. The first 60 cases treated with chenopodium gave an average of 99 hookworms. Among more recent treatments there have been much better results that the average of 99 in the first 60 chenopodium cases has increased to 131 in 90 cases. In one instance there were expelled 1,379 uncinariæ in the first whole stool. In summarizing they state that the method of administration of chenopodium is simple, and is attended with less inconvenience and discomfort to the patient than thymol. This would give the drug an important place in field work in uncinariasis. Chenopodium can be given at shorter intervals than can thymol, and a cure can thereby be more quickly established, which gives it a greater economic value. Chenopodium is non-toxic in therapeutic doses. It is a more efficient vermifuge than thymol in the treatment of uncinariasis.

5. **Creatin and Creatinin Excretion during the Puerperium and Their Relation to the Involution of the Uterus.**—Arthur Morse says that their conclusions are based on the observations of four types of cases, namely, (1) a normal labor; (2) a conservative cesarean section at the end of normal pregnancy; (3) a conservative cesarean section in a case of pre-eclamptic toxemia, and (4) two cases of cesarean section with removal of the uterus. A material so varied has enabled them to learn in the first place that the creatin and creatinin metabolism is practically identical after normal labor and after cesarean section, provided the uterus is not removed, and the pregnancy has not been complicated by a toxemia. From the observations made on four cases in which cesarean section was performed, in two instances without removal of the uterus, and in two instances with hysterectomy, the following conclusions may be drawn: 1. A lower total nitrogen output is observed in case hysterectomy is performed, and the higher output of nitrogen observed when the uterus is left *in situ* is explained by the involution process. 2. A lower creatinin output in case of hysterectomy and at least 2 gm. of this substance excreted during the puerperium arise from the involution of the uterus. 3. Creatin in large amounts regularly appears in the urine following childbirth. The creatinuria is independent of the involution of the uterus, and it is also independent of the creatinin metabolism.

6. **Elementary but Vital Factors in the Efficiency of Smaller Hospitals.**—L. W. Littig believes that a high-grade hospital must have a conscientious, progressive, united, and cooperating attending staff, integrated to educate and improve itself, and to discharge its duty alike to patients and to nurses in training; it must have a nursing staff under the guidance and control of a single, efficient, capable and authoritative head; it must have a general management which, hard pressed though it may be by financial considerations, remains ever sensitive and responsive to the best interests of its patients. In such a hospital, responsibility can always be fixed; untrained and poorly supervised girls are not assigned to special cases; the patients under the care of one nurse "on general" never exceeds a certain fixed minimum; there is not an unending chain of inexperienced girls at the instrument table, and an efficiency expert is rarely needed. This hospital will fulfil its high mission as an educator of the profession and the community in which it is located.

9. **Factitious Dermatoses.**—Oliver S. Ormsby records a group of cases of self-inflicted dermatitis, which have occurred during the last several years in the practice of the late Dr. James Nevins Hyde, the late Dr. Frank Hugh Montgomery, and himself. Of the 34 patients described, 30 were females. Fifty per cent. were under 22 years of age. Trauma preceded the lesions in 12 cases. Of the 34, 13 confessed, and made an immediate recovery; one case was proved under the care of a nurse, and three under fixed dressings; one patient completely recovered after being confronted. Of the 34, it was proved that 14 used phenol, four probably used phenol, one used compound solution of cresol, one phenol and other substances, one croton oil, one lye, one sandpaper, one tobacco, one the electric needle and unknown but liquid applications, six entirely unknown substances, and three unknown liquids. It seems probable that the major portion of the cases described as pemphigus gangrenosus are in reality examples of factitious dermatitis. That the major number of cases reported under the title "zoster gangrenosus atypicus" (Kaposi) are of the same type, and also those more recently described under the title of "dermatitis symmetrica dysmenorrhoica" seems probable. While the disorder is comparatively rare, it probably would appear more common if more generally recognized. On the recognition of the disorder, the admission of the patient as to its cause, and the cessation of the practice responsible for the condition, immediate recovery generally takes place; if not, the application of fixed dressings and surveillance day and night, if followed by the disappearance of the lesions and the non-appearance of new ones, will prove the diagnosis. The only difficulty in any case is to prove the diagnosis.

11. **Mounting of Specimens.**—Fred D. Weidman states that the fact that gross-morbid museum specimens when mounted in the usual way suffer greatly by handling has led him to make some experiments in mounting. Where the material is soft and will not stand pressure it is arranged face downward on a smooth-soaped surface. A wall is built around it en-

closing a space about one cm. larger than the inside dimensions of the face of the container, which must be rectangular for the proper use of this method, and the inside of the walls was also soaped. Plaster of Paris was then poured over the specimen until it was of a depth equal to the narrowest antero-posterior dimensions of the container. As soon as the plaster has hardened, the walls are torn down and the slab of plaster with the contained specimen is lifted from the glass. The whole is, when perfectly dry, slipped into the container and covered by mounting fluid. It should not be sealed for several days until bubbles have ceased to accumulate. This method is particularly adapted to all kinds of worms, except the thicker ones, or to serial slabs of brain. The author describes his technique in detail.

12. **Osteochondritis.**—George J. McChesney calls attention to the condition described by Professor George Perthes of Tübingen as juvenile deforming osteochondritis since it is a condition liable to be confused with tuberculosis, juvenile deforming arthritis, polyarticular acute arthritis, coxa vara, and osteomyelitis. It is characterized by a progressive destruction and crushing, principally of the upper femoral epiphysis. Its symptoms are a slight limp, a fairly constant limitation of abduction and a benign course with complete recovery under little or no treatment. The disease appears when the child is in good health and is not especially concerned with any specific trauma, although in two or three cases mild injuries were associated with the onset. Slight shortening and atrophy were occasional symptoms of lesser note. Pain was an almost negligible factor. Specimen examined microscopically showed a delay in ossification of the cartilage of the epiphysis, and to a lesser extent also in the juxta-epiphyseal cartilage of the neck and isolated areas in the acetabulum. Calcareous nodules or dark spots of the ossific nucleus of the epiphysis have also been noted. As a result flattening or crushing of the epiphysis occurs, because cartilage persists where bone is needed. Perthes, who has studied the condition more thoroughly than any one else, concludes that operation is not needed, that correction of the abduction under anesthesia may be a good procedure, and that plaster spicas do no harm beyond inducing some atrophy, but that extension with massage is probably better. The writer emphasizes the importance of differentiating this condition from tuberculosis as the wearisome course of treatment indicated for tuberculosis is not required in osteochondritis.

14. **Autolysin.**—Richard Weil states that since January 1, 1915, 23 cases of cancer have been treated in the Memorial Hospital by Dr. Beebe with so-called autolysin. The cases were all considered hopeless. Of these 23 patients, 14 have since died and eight were discharged, unimproved. In only one instance could the condition of the patient be described as improved. In view of the fact that patients are coming even from distant States with the hope of securing relief from suffering, and in many instances at serious financial sacrifice, the writer believes it his duty to relate what has come under his observation in reference to the use of autolysin in cancer, and states that it is his personal belief, founded on long observation, that this remedy is useless and adds nothing of value to the methods now generally accepted, and that it often aggravates the sufferings and accelerates the death of the patient.

2. **Pellagra Considered from the Point of View of a Disease of Insufficient Nutrition.**—F. M. Sandwith says that pellagra has been known to the world for at least two centuries, and yet we are still in vague doubt about its etiology. There are four prominent theories under consideration to-day. 1. That the disease is in some way associated with maize. 2. That pellagra is a protozoal disease, probably transmitted and propagated by a *simulium* or by some other insect. 3. That pellagra "is contracted in definite zones where the usual drinking water comes from springs arising in argillaceous soil, or from the streams and stagnant pools in a clayey district." 4. That pellagra is due to a streptobacillus found in the blood, cerebrospinal fluid, and feces during life, and in organs after death. After having studied many hundreds of cases he presents his beliefs regarding the etiology of pellagra. With regard to the relation of pellagra to maize he says he imbibed the belief that good maize could not produce pellagra under any circumstances, but that it must be caused by some deterioration in that cereal, due to faulty harvesting, drying, or storage. Soon he began to consider that this disease was not caused by what a man ate, but what he failed to eat. If this view was eventually proved to be incorrect he was prepared to change his belief; but in the meantime he was of the opinion that attention should be drawn to the analogy existing between the historical beliefs concerning beriberi and pellagra. The points of resemblance between the two are as follows: 1. The head-louse and many other insects have been accused of conveying beriberi. 2. Many chemical poisons have been suspected in both diseases, besides intoxication from some germ in the food or in the dwelling. 3. Beriberi was thought to be a protozoal disease and that the causal factor was eliminated by the urine, while other animal parasites have been suspected, including *Ancylostomum duodenale*, which is so common a companion of pellagra. 4. Cocci, bacilli, and fungi have all made a temporary appearance upon both stages. 5. Both diseases in endemic countries affect the laboring classes. 6. The belief that beriberi is communicable from one person to another is still held by some. 7. In beriberi and pellagra infants are seldom attacked. 8. Sceptics still maintain that beriberi cannot be due to a deficiency connected with rice, because beriberi sometimes exists in countries or in individuals when no rice has been eaten. It is also contended that pellagra can have nothing to do with maize, because it has been discovered in non-maize-eating people. The association between beriberi and rice is almost accidental. Beriberi is a deficiency disease and presumably might occur after any diet in which the necessary substance is not present. It is this essential substance that C. Funk has given the name "vitamines." If it can be proved with regard to beriberi and pellagra that the vitamines are absent it does not matter whether the basal cereal diet is rice, maize, or anything else. The earliest descriptions of pellagra associate it with insufficient diet. Experiments make it obvious that the best conditions have been worked out and that it is certain that "bad" maize does not produce

any deleterious results in short periods of a month to six weeks, even under circumstances most favorable for its action. This throws out of court all the short experiments so prevalent in the literature about pellagra.

3. **The Treatment of Cerebrospinal Fever in the Royal Navy.**—H. D. Rolleston says that from the commencement of the war to July 31, 1915, there have been 170 cases of cerebrospinal fever in the Royal Navy. A summary of the results of treatment is abstracted from the notes of 163 cases, eighty-nine, or 54.6 per cent., of which proved fatal. Various forms and combinations of treatment were employed, and the most noticeable point brought out is the failure of the generally approved intrathecal injection of antimeningococcic serum. The failure of this serum to reduce the mortality was not due to its being given too late, for in 66.7 per cent. of the 105 cases (sixty-four, or 61 per cent., died, and forty-one, or 39 per cent., recovered) it was administered within the first three days of the disease. The serum treatment, which was so successful in America (Flexner, Sophian), Belfast (Robb), and elsewhere, was given a thorough trial and has proved most disappointing. In very few instances was there the critical improvement which is said to occur in about 30 per cent. of the cases that recover (Flexner). The use of soamin appeared to give good results. Hexamine given by the mouth did not appear to have any effect clinically and was soon abandoned. Lumbar puncture, which is such an important means of diagnosis, was performed in 149 out of 163 cases, or in 91.4 per cent. In thirty-eight cases lumbar puncture was done once only, but fourteen of these cases died soon after they came under observation; six other cases, tapped once, died. Of twenty-two cases tapped twice eight proved fatal, two being very acute; three tappings were done in twenty cases (nine deaths), four in twenty-four (fifteen deaths), five in fifteen (nine deaths), six in six (three deaths), seven in seven (four deaths), eight in three (two deaths), nine in four (all fatal), eleven in five (two deaths), 13 in one (fatal), fifteen in one (fatal), sixteen in one (fatal), and seventeen in two (both recoveries). Lumbar puncture appears to be a palliative rather than a curative remedy and to relieve for a time symptoms due to increased intrathecal pressure. In thirteen cases, of which four proved fatal, it was the only form of treatment other than the ordinary symptomatic remedies employed. In fourteen cases, ten of which proved fatal, symptomatic remedies only (such as morphine for pain) were given.

6. **Nystagmus and Allied Conditions.**—James Alexander Wilson gives some details of 200 consecutive cases of nystagmus with some deductions. This condition is more prevalent in youth and tends to disappear in adult life. The following cases of abnormal movements of the orbital muscles are allied to nystagmus and may throw some light on its etiology: (1) Associated movements of the eyelids and jaw, or "jaw-winking." (2) A child with one eye wide open while crying. (3) Rhythmic closure of the right eyelids. This occurred about once a minute. He reports another group of cases of so-called cyclic affections of the third nerve. Here the third nerve is paralyzed and yet rhythmic contractions occur in the muscles supplied by the affected nerve. Ten per cent. of the cases were the result of ophthalmia neonatorum. There were other examples of the far-reaching effects of sexual impurity. The writer advises that spectacles to correct errors of refraction and operative measures that might improve vision should be adopted as soon as possible. Atropine applied to the eyes sometimes makes the oscillations worse. Eserine does not do any good.

7. **The Effect of Nauheim Baths upon the Cardiac Conductivity and Contractility.**—Leslie Thorne Thorne emphasizes the fact that the Nauheim baths can be given in London or elsewhere quite as satisfactorily as in Germany. In a large number of cases of cardiac and circulatory impairment the only indication of a defective conductivity is a slight lengthening of the a.c. interval. When sufficient time has passed to allow observers to follow up such cases over long periods, he believes it will be found that this slight impairment is the first indication of a condition which, if untreated, leads ultimately to serious defects in the nervomuscular mechanism of cardiac conductivity.

8. **Anesthesia (General and Spinal) for Suprapubic Prostatectomy.**—J. D. Mortimer says that in recent times it has been more and more evident, both by clinical observations and by investigations in the laboratory, that anesthetics given by inhalation do not annul nervous impressions due to injury, surgical or otherwise, although they more or less diminish or modify them. Some years ago he drew attention to some of the dangers and difficulties arising during prostatectomy under general anesthesia. It must not be supposed that these difficulties and dangers invariably occur. In nearly 300 operations done at St. Peter's Hospital, for which he gave a general anesthetic alone, they were noted as having happened in less than 12 per cent. Still they should always be prepared for them. Spinal analgesia not only prevents reflex disturbances but is less likely to be followed by suppression of urine. As a rule when the patient is weakly or nervous it is advisable to combine it with light general anesthesia to avoid mental distress or "psychic shock." Combined general and spinal anesthesia answers well for many operations, such as the removal of piles, external urethrotomy, and particularly for the radical cure of hernia in infants and young children.

10. **A Case of Tapeworm Accompanied by Hemoglobinuria.**—W. E. Masters reports this case. It was of interest because of a very severe hemoglobinuria that suddenly followed the expulsion of a tapeworm by male fern after the patient had taken "four bottles of beer." In this case it appears as if the alcohol, together with the unexcreted male fern, acting upon a weakened constitution, freed the latency to hemoglobinuria.

1. Analysis of Cases of Tetanus Treated in Home Military Hospitals from August, 1914, to August, 1915. David Bruce.
2. On the Hemolytic Action of the Urine in Certain Conditions. C. S. McKee.
3. Ureteral Calculus: Its Symptoms and Treatment. David Newman.
4. Epidemic Jaundice in War Time. S. Moritz.
5. Malaria Contracted in Flanders. J. McG. H. Reid.

1. **Tetanus Treated in Home Military Hospitals.**—David Bruce discusses the results of various methods of treatment in cases of tetanus in the home military hospitals as shown by the records of 231 cases treated in these hospitals since December, 1914. He finds that in this series of cases the mortality was 57.7 per cent. Cases with a short incubation were more fatal than those of longer incubation. Most cases occurred on the tenth day after the wound. There are few allusions to the use of antitetanic serum as a prophylactic. In regard to the therapeutic effect of antitetanic serum the evidence would go to show that this action was not well marked. If antitetanic serum is used—and in such a fatal disease it would seem wrong not to give the patient the benefit, even if doubtful, of the antitoxin—it ought to be injected in the first place intrathecally, as this method would seem to possess advantages over the intravenous and subcutaneous methods. There was no evidence that any benefit accrued to the cases treated by

carbolic acid or magnesium sulphate injections. This analysis suggests that the treatment of a case of tetanus might be about as follows: 1. Place the patient in a quiet darkened room under the care of a sympathetic and capable nurse. 2. The best surgical treatment of the wound should be carried out to insure the prompt and complete removal of all septic products. 3. An intrathecal injection of at least 3,000 units of antitetanic serum should be given. At the same time 10,000 to 20,000 units may be injected intravenously or subcutaneously. This procedure might be repeated as frequently as the course of the disease seems to demand. 4. In addition to this, the author says, the patient should receive certain sedative drugs, such as chloral or chloretone, in full doses.

2. **Hemolytic Action of Urine.**—C. S. McKee states that this investigation was carried on with the intention of noting if after the red corpuscles had been exposed to the action of urine there was any increase or decrease in the resistance of these to the action of a hemolytic serum, or any other change which could be noted or followed up. After describing his technique the writer states that so far he has never observed hemolytic activity in the urine of healthy persons, but finds that this appearance of a body or bodies in the urine of a more or less hemolytic nature is a fairly frequent accompaniment of grave disturbances of metabolism. In severe anemia the reaction is frequent, but not of daily occurrence. After having tested the cells of several pernicious anemia cases he found that the cells of some patients were more resistant than those of others, but also that all were less resistant than normal cells. The reaction was obtainable in erysipelas, gout, acute rheumatic fever, advanced tuberculosis, and certain cases of syphilis, in all severe burns, and in some cases of skin disease in which a large part of the skin surface had been involved, in carbolic-acid poisoning, cancer with wasting, in diabetes if coma was approaching, and in four cases of pregnancy during the last week, all of which became eclamptic. There is also a group of kidney and heart cases that exhibit urinary hemolysis. The agent causing this hemolysis is left an open question, but there seems no doubt that it is not a normal constituent of urine. Save in the case of strongly hemolytic alkaline urines, of which one drop sometimes causes an instant laking of the blood emulsion at room temperature, the hemolytic process requires incubator temperature of 37° *in vitro*, and possibly when administered to the patient by mouth. A curious and apparently definite grouping of stable and unstable urines so far as change of reaction from acid to alkaline is concerned has been remarked. This group of unstable urines may perhaps be found of prognostic value.

4. **Epidemic Jaundice in War Time.**—S. Moritz makes a study of epidemic jaundice which shows that the largest epidemics have occurred in war time. He thinks there is no doubt that epidemic icterus is a disease *sui generis*, due to some infective agent. The infection seems to be due to a virus or organism which develops in the soil during the decay of organic matter, and hence undoubtedly bad camp conditions were the principal cause of the large epidemic in the American war. In this war, in round numbers, out of 1,087,000 men in the Atlantic army, 22,000 fell ill with icterus; of 1,100,000 men of the Central army 20,500 became infected; while of 30,000 of the Pacific army only 100 became icteric. In regard to the differential diagnosis simple catarrhal jaundice, recurrent fever, and bilious typhoid fever come into the question. Until the microorganism of epidemic jaundice is found it will be impossible to distinguish slight cases of this illness from simple catarrhal jaundice. In some epidemics of recurrent fever many of the cases are affected with jaundice; the presence of spirillæ in the blood will clinch the diagnosis. As icterus is said to interfere with the Widal reaction the differential diagnosis from typhoid may be difficult. In 1886 Weil of Heidelberg described a small number of cases, and since then "epidemic jaundice" has been described under the name of Weil's disease not only in German but also in English textbooks.

Münchener medizinische Wochenschrift.

September 28, 1915.

Relations of Life to Light.—Schanz states that the albumins are photosensitive, and that light changes readily solubly forms to those which dissolve with difficulty. Catalyzers exist in nature which promote this transformation such as chlorophyll. This may readily be demonstrable. A solution of serum albumin when placed in the light begins to change the latter into globulin. If chlorophyll is added this change is accelerated. A very powerful catalyzer of this type is hematoporphyrin, an iron-free derivative of hemoglobin. When some of this coloring matter is injected into the circulation of a white mouse, even the light of a Vienna spring day is sufficient to kill the animal. The form of death has been termed "light-stroke." When acute the animals first develop an intense itching, photophobia, and redness of the ears and within two or three hours die in tetanic spasms. By making the light exposure less intense a more chronic course is pursued. The animals swell out of shape, the ears assume a characteristic contour, the eyelids adhere and perhaps eventually the ears become gangrenous and the hair falls out. A study of this subject of light catalysis tends to throw doubt on the supposed properties of animal coloration and pigmentation. Colors have been held responsible for sex attraction, defense, etc., when there was no proof that the animals in question possess any color sense. This is true, especially of marine life. The claim has recently been made that only animals who dwell in the atmosphere can have color perception. To take up the question of the function of human pigment, the author claims that it is a negative light catalyzer which protects the albumin in the integument from injury. Animal pigment is the reverse of chlorophyll, a positive light catalyzer. A mystery of the ages is the office of the color of flowers. In the lack of a utilitarian motive religious philosophers have claimed that flowers are of teleological significance, in that they assert an esthetic sense in the Deity which is a counterpart and source of our own instinctive love of the beautiful. The author disproves the bee attraction theory because bees are color blind. For him the color in flowers is a photocatalyzer, evidently positive like the chlorophyll of the leaves, and meant to bring about certain transformations of albumin in the fruit germ which lies beneath the flower.

Observations in Typhoid Immunes.—Ziersch has made a close study of individuals who have been vaccinated against typhoid fever. His conclusions which are brief are as follows: After the vaccination leucopenia soon sets in, just as in typhoid itself. This leucopenia can be demonstrated in the blood for months afterwards with complete regularity. There is no "negative and positive phase" to be seen after the inoculation. The percentage blood picture shows analogies with that of the genuine disease save for absence of eosinophilia which does not appear. In the immunized the Gruber-Widal reaction shows no regularity in any respect. After the author's paper was completed he was made aware of another on the same subject by Stieve (*D. Arch. f. klin. Med. Bd.*, 117), whose finds are in harmony with his own.

Insurance Medicine.

The Organs of Special Sense in Life Insurance.—In a paper read before the fifth midyear meeting of the Medical Section of the American Life Convention, Dr. William A. Peterson, Medical Director, Scandia Life Insurance Company, brought out the fact that in examination for life insurance special stress is laid on the careful study of the heart, lungs, and kidneys, while the organs of the special senses are often given a careless review or overlooked altogether.

An artificial eye is sometimes not recognized or noted, thus showing how little attention is paid to the eye. Of the organs of special sense the eye affords more information for diagnostic purposes concerning the condition of other organs than any single part of the body which may be examined. The conjunctiva, crystalline lens, and cornea often give evidence indicating the general systemic condition. Inflammation or redness of the eye may be due to gonorrhea, catarrh, or some other acute or chronic infection. Subconjunctival ecchymosis may indicate epileptic seizure, asthenia, or severe dyspnea. The sclera and cornea are indicative of existing conditions; for example, jaundice by a yellowish hue, an arcus senilis in segments, one above and another below at the sclerocorneal junction, indicating some fatty degeneration of the tissues of the body, arteriosclerosis, atheroma, or chronic nephritis. An old healed ulcer of the cornea may mean some past syphilitic condition. The pupillary reaction to light and accommodation may be observed, and should never be omitted in any physical examination regardless of health or condition of the applicant. The well-known Argyll-Robertson pupil is known to occur in a large percentage of cases of locomotor ataxia, intracranial syphilis, and paresis, and, indeed, it is often an early symptom of these diseases.

The visual field may be readily tested by having the applicant close one eye and look straight ahead and then take his range of vision while observing your moving finger without changing position of the eye from fixation point. Any change in the field may be an important factor in judging the applicant for life insurance. Such condition may be due to toxic substances as in tobacco or alcoholic poisoning, or it may be due to diabetes, multiple sclerosis, or acute degenerative nervous diseases. Sudden blindness of one eye may be due to embolism or thrombosis of the central retinal artery or cerebral hemorrhage involving the central visual path, and may be so marked in degree as to bar the applicant without any further examination or even so much as a determination of its cause.

While the study of the interior of the eye is very important, it cannot be made in the ordinary life insurance examination, unless carried out in a properly equipped office. For this a dark room equipment and an understanding of the use of the ophthalmoscope are necessary. With the light thrown into the eye any changes in the interior may be readily noted. "Choked disk," if present, will give a clue to either a brain tumor, especially in the cerebrum, meningeal inflammation, tuberculous in origin, or possibly to some acute febrile disorder, syphilis, toxemia from lead or alcohol, rheumatism, or anemia. A reddened optic nerve with edges irregular and obscure, and the veins enlarged and tortuous, suggests optic neuritis, indicating some intraorbital or intracranial disease. Again optic atrophy may be present, usually indicative of locomotor ataxia in about thirty per cent. of cases; also in paretic dementia and disseminated sclerosis this condition may be found.

A retinitis may be found, the most common and important form of which is albuminuric, due to Bright's disease or diabetes. Hemorrhage into the retina generally results from septicemia, ulcerative endocarditis, hemophilia, diabetes, gout, and malarial fever of a severe type.

A thorough study of sight and the eye in examination for life insurance often reveals hidden and obscure diseases having no other symptoms. Every examiner should be able to make a thorough examination of the eye muscles and their movements and to make an intelligent interpretation of his ophthalmoscopic findings.

From the life insurance point the sense of taste, situated principally in the tongue, would not be of great importance but for its close relation to the sense of smell. When smell is defective an examination of the nose should be made to ascertain whether the loss of olfaction is due to some nasal obstruction or to more or less serious defect in the nervous mechanism.

Sensations or feeling of the skin may be divided into four parts: tactile, pain, temperature, and pressure sense. Any one of these senses may be perverted or in abeyance without the others being affected in a similar manner. Each part of the skin has a sensitiveness of its own. The two chief manifestations of perverted sensibility in the skin are anesthesia and hyperesthesia. The organic causes of anesthesia of the skin are cerebral hemorrhage, cerebral tumor, hemorrhage or tumor of the pons, hemorrhage or tumor of the cord, myelitis, locomotor ataxia, pressure on the posterior nerve roots, and paralysis of nerve endings. Hyperesthesia of the skin occurs in hysteria and neurasthenia, in peripheral neuritis and locomotor ataxia, brain tumors, alcoholic excesses, and diabetes. Thus it will be seen that no definite diagnosis can well be made from skin sensation alone, but in conjunction with other symptoms it is of great value.

The ear is important from an insurance standpoint. Otitis media is one of the most common and important affections and usually dates back to an acute disease. Pain in the ear may be due to a tooth condition, alveolar abscess, or mastoid disease. It may be one of the stigmata of degeneration, especially when unusually prominent or misplaced with absence of helix, anthelix, or concha. Different types of sounds when continuous or intermittent are indicative of middle or internal ear conditions or meningeal inflammations. Musical sounds are indicative of some central lesion. Deafness is usually due to disease of tympanum, middle ear, or Eustachian tube, or it may be due to disease of the auditory nerve, its muscles, or its cortical center. Chronic deafness, if marked, impairs the risk and suppurating ears speak against acceptance.

This brief paper shows that the condition of the organs of special sense is of great importance in life insurance examinations and should not be overlooked.

Book Reviews.

PRACTICAL MATERIA MEDICA AND PRESCRIPTION WRITING. With Illustrations. By OSCAR W. BETHEA, M.D., Ph.G., F.C.S. Assistant Professor of Materia Medica and Instructor in Prescription Writing, Tulane University of Louisiana. Formerly Professor of Chemistry and Professor of Pharmacology, Mississippi Medical College, etc. Philadelphia: F. A. Davis Company, 1915.

IN this new work the author includes all the official drugs and a few of the non-official preparations. He wisely devotes most space to those drugs which are most frequently used, while those which are seldom prescribed are not discussed in detail. The book has a large number of prescriptions, most of which are taken from well known and standard works on Practice, etc. There is an important section on prescription writing which should prove of value; and the author's criticisms on the several prescriptions are, as a rule, well founded and worth reading. There is one important omission; no reference is made to the Harrison law concerning opium and other narcotics. Two indexes render the contents of the volume readily available. For the busy practitioner this is one of the most serviceable of the many books on Materia Medica at his disposal.

A GUIDE TO THE USE OF TUBERCULIN. By ARCHER W. R. COCHRANE, M.B. London, F.R.C.S. England, and CUTHBERT A. SPRAWSON, M.D., B.S. London, M R.C.P. Price, $2.25. New York: William Wood & Co., 1915.

THIS little volume, consecrated to the discussion of tuberculin, although not bringing forth anything new, covers the ground most thoroughly. Chapter I treats in a general way of the rôle tuberculin plays as a therapeutic agent by stimulating healing in the diseased area and by preventing the spread of the disease. In Chapter II, no less than fourteen varieties of tuberculin are enumerated, which in itself must be somewhat bewildering to the inexperienced practitioner when it is admitted that these culture products differ considerably in their reaction. Of greatest value are perhaps the chapters on technique and dosage for the results depend so much on this. The authors' statement in Chapter X, that of those who come to them for treatment, the majority are suitable—roughly about 75 per cent., is evidence of their enthusiasm. This is a much higher percentage of cases treated by tuberculin than in any of the American institutions or by American practitioners. After the enumeration of the well-known contraindications the reviewer was surprised to read the following: "On the other hand, we hold pregnancy *per se* to be a most strong and compelling reason for the administration of tuberculin and the highest doses should be aimed at toward the end of the period." This opinion is not shared at this time by many phthisiotherapeutists, general clinicians, and obstetricians. It is fortunate that the authors can claim good results from this truly heroic treatment, and when one recalls the utter hopelessness of so many cases of pregnant tuberculous women, one cannot help feeling grateful that the authors have shown a way whereby at least some of these unfortunate women can be saved. The little volume has no less than eighty-four charts showing fever-curvatures as a result of tuberculin treatment which for the student of this difficult therapy are of greatest value. The book certainly deserves a careful study by those who desire to familiarize themselves with tuberculin treatment.

HABITS THAT HANDICAP—The Menace of Opium, Alcohol and Tobacco and the Remedy. By CHARLES B. TOWNS. Price, $1.20 net. New York: The Century Company, 1915.

THE drug habit is widespread and menacing and is said to be unduly prevalent in this country. It is impossible to arrive at the true situation in this respect for reliable statistics dealing with the question are not available. There probably is a certain amount of exaggeration on the point, but that the drug habit exists to a considerable extent in the United States is doubtless beyond cavil. The methods of treating the habit have been many, most of which have failed. Mr. Towns appears to have been successful in this direction and a perusal of his work conveys the impression that his modes of treatment are founded on scientific commonsense principles. The work is interesting and deserves to be read by members of the medical profession.

PRAKTIKUM DER CHIRURGIE. Ein Leitfaden für Ärzte und Studierende. Von Dr. O. NORDMANN, Oberarzt der chirurgischen Abteilung des Auguste Viktoria-Krankenhauses, Berlin-Schöneberg. I. Teil, Allgemeine Chirurgie, seiten 216 mit 90 teils farbigen Abbildungen. II. Teil, Spezielle Chirurgie, seiten 416 mit 161 teils farbigen Abbildungen. Price, I. Teil, 5 Mark; II. Teil, 10 Mark. Berlin and Wien: Urban & Schwarzenberg, 1915. The Rebman Company, New York Agents.

THIS is a very practical work for both the student and practitioner. Nordmann has not followed the rather customary plan of dealing with each surgical disease in schematic fashion—first describing the clinical course of the disease and its pathology, then diagnosis, therapy, special operative measures, etc.—but has brought out rather those points which seemed to him the most important and has drawn upon his own experience in the main rather than making extensive references to the literature. The result is, therefore, an eminently practical surgery where the salient features are emphasized and but little time is wasted over the non-essentials. We find, for example, considerable space given to diagnosis in those cases where there might be difficulty in differentiating from some other affection; to treatment, when there may be a choice of several methods or when the operative technique varies with the progress of the disease.

The first volume is divided into twenty chapters and is concerned with general surgery. Beginning with chapters on the armamentarium, local and general anesthesia, hand disinfection and the preparation of the operative field, the author passes to the consideration of wounds, injuries, and infections of all sorts affecting the soft parts and the various complications that may arise, together with their treatment, acute osteomyelitis, diabetes in surgery, surgical tuberculosis, and various other subjects appropriately grouped under the heading "general" surgery. The final chapter deals with the recognition of the various types of tumors and their treatment in general.

The second volume, comprising thirteen chapters, deals with special or regional surgery, the last seventy-five pages being devoted to fractures and dislocations. This volume, already of great practical value, has been enriched here and there by additional material based upon personal experience during the first five or six months of the present war.

Considering the work as a whole, we find that although, in many instances, German practice differs from ours, the work seems to be based upon sound teaching and experience, and is rather unique in its avoidance of wholesale borrowing from the literature. We believe it would form a worthy addition to any surgeon's library; while it should be even more valuable to the younger man whose knowledge of surgery and surgical problems is mostly theoretical, rather than a product of experience.

DISEASES OF THE NERVOUS SYSTEM, a Textbook of Neurology and Psychiatry. By SMITH ELY JELLIFFE, M.D., Ph.D., Adjunct Professor of Diseases of the Mind and Nervous System, New York Post-Graduate Medical School, and WILLIAM A. WHITE, M.D., Professor of Nervous and Mental Diseases, Georgetown University and George Washington University, lecturer on Psychiatry, U. S. Army and U. S. Navy Medical Schools. Price, $6.00 net. Philadelphia and New York: Lea & Febiger, 1915.

IN the construction of this book, the authors "have kept in mind the concept of the individual as a biological unit tending by development and conduct toward certain broadly defined goals and have considered the nervous system as only a part of that larger whole." To this end the work has been divided into three parts dealing respectively with the vegetative, the sensorimotor, and the psychic levels, the reactions in all of which come to pass through the medium of the nervous system. In adherence to this plan there is included a chapter on the endocrinopathies some of which perhaps do not properly belong in a book on diseases of the nervous system. This is a distinct gain, however, and the work makes one continuous story from start to finish. The whole subject of syphilis is treated in a chapter by itself. The plan is not without difficulties but they have, for the most part, been met satisfactorily. The result is an exceedingly attractive volume which, though brief, is nevertheless complete in all essentials, is thoroughly up-to-date, and is, moreover, very practical.

Society Reports.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

Forty-first Annual Meeting, Held at Lexington, Ky., October 19-21, 1915.

(*Concluded from page 852.*)

THE PRESIDENT, DR. HUGH CABOT OF BOSTON, IN THE CHAIR.

Caudal Anesthesia for Prostatectomy and Other Genitourinary Surgery.—Dr. BRANSFORD LEWIS of St. Louis reported seventy-seven cases in which this method of anesthesia was used with gratifying results. The method was far preferable to the other methods which entailed difficulties and disappointments.

Dr. CHARLES E. BARNETT of Fort Wayne, Ind., said he thought the mortality of prostatectomy was due more to general anesthesia than any other one thing on account of the deficiency of the kidneys in these cases, and the sooner we could get away from general anesthesia, the less the mortality would be following prostatectomy, no matter what route we adopted in removing the prostate.

Dr. JOHN W. DEAL of Springfield, Ill., stated that in speaking of the high mortality, he would like to ask whether reference was made to gas followed by ether or gas with the occasional administration of ether, as given by Crile and Frank.

Dr. RICHARD A. BARR of Nashville said some three years ago, Dr. Brown of Nashville noticed an account in a German medical journal of this method of anesthesia, and he immediately adopted its use and advocated it, and it had been quite generally used in his city by a number of different surgeons for rectal work. He had done a little rectal work and a few perineorrhaphies by the method and had found it entirely satisfactory in the few cases in which he had used it.

Dr. FILIPP KREISSL of Chicago said in regard to local anesthesia and nerve blocking, he wished to recommend that the members of this association, who were interested in this subject, buy the book of Dr. Braun, a German physician, which was published four or five years ago from which most physicians had obtained their information with regard to this method of anesthesia. The methods of local anesthesia for operations on the pelvis, bladder, and prostate were intraspinal, epidural or sacral, and parasacral. The dangers of injecting the epidural canal with novocaine or cocaine, and the dangers of nerve blocking with novocaine, were grossly exaggerated. If one would keep well within established and safe limits of this drug, not using more than a definite quantity of a certain concentration, there was absolutely no danger to be expected from the use of novocaine.

Dr. STANLEY G. ZINKE of Richmond, Ky., said as to caudal anesthesia, the sacral canal was a cavity or sac, and we required from 30 to 90 c.c. of the agent we used before we got the anesthetic effect. Why? Because the capacity of these little sacs differed. The anesthesia was due entirely to pressure and not at all to the novocaine present, one-half of one per cent. It made no difference what quantity was injected, it was the pressure that did the work and not the cocaine or the novocaine.

Dr. LEWIS, in closing, said in answer to Dr. Deal's question concerning gas and ether, the statistics he gave were not analytical. He did not think it was necessary to go into the statistics of mortality of general and local anesthesia.

When Is a Prostatic Fit for Operative Procedure?—Dr. CHARLES E. BARNETT of Fort Wayne, Ind., said after the maximum benefit from thorough preoperative treatment found the patient below par in fitness for operative procedure, the question of the anesthetic given should be the most considered. The less the fitness, the less the general anesthetic. Local anesthesia, when possible, and to the greatest degree, when not possible, was the one to be chosen. It appealed to the speaker that if the general practitioner who was the most deeply interested party toward his patient's welfare, would investigate the results of these simple tests, which were so positive for a favorable or fatal ending, then all parties concerned in the operation would be benefited.

Dr. BEN MORGAN of Chicago said the effect of local anesthesia on the kidneys was less deleterious. Local anesthesia in surgical operations upon the prostate should come first in conjunction with a general but mild anesthetic, and what general anesthetic should be preferred? Chloroform? No. Ether? Doubtful. Nitrous oxide? Yes.

Dr. W. D. HAINES of Cincinnati said we were living under a very high pressure mentally and physically, but the surgeon's duty, especially in this type of cases, was to save life, not to save time. The preoperative management of cases of prostatic disease was infinitely more important than what the surgeon was going to do at the operating table. It was not a hard job to take out the prostate. Almost any general surgeon could do it, but the experienced man who had handled many cases would have a high mortality if he did not heed well the warning this paper carried to us.

Dr. J. B. TAULBEE of Lexington, Ky., stated that he was favorably impressed with nitrous oxide as an anesthetic. His experience with ether in doing prostatectomy had convinced him that in these cases in old men, where the system was run down it was better to forego the operation than to risk a general anesthetic as ordinarily given, whether it was ether or chloroform. The safest method was to do a two-stage operation under local anesthesia.

Dr. BARNETT, in closing, said he was glad to hear Dr. Morgan bring out the point that no general anesthetic was good for a prostatic except nitrous oxide-gas. Dr. Haines brought out the most important point of the whole subject, namely, to take plenty of time in preparing the patient for operation.

Autogenous Vaccines in the Treatment of Bronchitis and Asthma.—Dr. ROBERT H. BABCOCK of Chicago drew the following conclusions: 1. Autogenous vaccines prepared from the sputa had yielded such results in three cases of acute bronchitis, one of chronic bronchitis, and four of chronic bronchitis associated with attacks of spasmodic asthma as to warrant the writer in recommending this mode of therapy as against the old time use of expectorants by mouth. 2. In bronchitis independent of asthma, the organisms have been mainly of *Bacillus mucosus*, the *Diplococcus muscosus*, the *Micrococcus catarrhalis* and an influenza-like bacillus, while in cases of bronchial asthma an anaerobic fusiform bacillus had been added. 3. The asthma had yielded to this vaccine treatment only when this anaerobic fusiform bacillus had been largely present in the vaccine. 4. Great care should be exercised in the use of vaccines that the dosage be not so large or so often given as to cause reaction, since this reaction, whether general or local, indicated a negative phase and aggravated the patient's condition. 5. The main drawback to the use of autogenous vaccines was the necessity of perhaps several cultures and the preparation of new vaccines should the cultures show that some of the originally found germs had disappeared or become subordinate in number to others. 6. New vaccines should be prepared whenever the condition of the patient seemed to have come to a standstill.

Dr. LEON SOLOMON of Louisville said expectorants, both the so-called stimulating and sedative medicines must take a back seat with the advent of vaccine therapy. His experience with vaccines included not only autogenous vaccines, but it included to even a larger extent the socalled stock vaccines. Their employment in properly selected cases was fraught with as many and as positive results as those obtained from the use of autogenous vaccines. The fusiform baccilli to which the essayist referred in the cases reported had been entirely absent in any case under his observation, as well as that of a competent bacteriologist in a thoroughly equipped laboratory. Perhaps the fusiform baccillus was common to Chicago and to the colder districts, from which in all probability Dr. Babcock's cases had come, although he did not refer to a gentleman from the South who came to him suffering from asthma.

Dr. F. M. POTTENGER of Monrovia, Cal., said the most gratifying feature in connection with this paper was that it came from the worthy pen of a teacher to whom we had always turned with great confidence. This fact alone rendered the knowledge presented of great value.

Dr. BABCOCK, in closing, said that with reference to Dr. Solomon's remarks concerning fusiform bacilli, one reason they were not more frequently obtained in the culture was that this bacillus grew very slowly. His laboratory reports showed that frequently after

all other bacilli had put in an appearance the anaerobic bacilli would fail to become manifest until after the third and sometimes the fourth day. He did not think the fusiform bacillus was peculiar to Chicago. In cases of bronchial asthma, when an alveolar abscess was present in any given case, the cultures in that case would show two organisms, the *Streptococcus mucosus* and the anaerobic fusiform bacillus. He was not prepared to say that this was the organism which was responsible for the asthma; nevertheless, it had been a striking experience in every one of his cases of alveolar abscess, with one exception, a fusiform bacillus had been cultivated from an abscess when the procedure had been allowed to extend over a sufficient length of time.

President's Address: Medicine, a Profession or a Trade.—Dr. HUGH CABOT of Boston, Mass., said medicine had always been regarded as one of the learned professions and indeed this was a distinction of which we were particularly proud. But the tendency of a profession to degenerate into a trade was ever present and was a danger from which more than one learned profession had been unable to escape. If medicine was to avoid the downfall which had overtaken the law, it would be because we were more conscious of the dangers or more alert to check at the beginning undesirable developments. To him a profession was an occupation requiring an education in science and which was pursued for its own sake. It must have the advancement of science or the benefit of mankind as its chief end, pecuniary advantage being always a secondary and subordinate consideration. A trade, on the other hand, was an occupation which was pursued chiefly, though not wholly, for the purpose of acquiring wealth; this wealth with its ability to advance the interests of the individual being the chief end. In estimating the importance of any development in medicine we could best do so by comparing present conditions with those of the past. The changes which had taken place and the effect which they had produced upon the prevailing type of practitioner stood out clearly if we looked back and pictured to ourselves the type which was looked upon as the highest twenty years ago and compared it with the best that we were producing to-day. The big men of twenty years ago had, without exception, gone through this school of general practice and had risen to the ranks of eminence by sheer force of character, being largely without assistance of the laboratory, and having fewer instruments of precision than we possessed. They had trained their faculties of observation in the hard school of experience and had come to rely far more than we did to-day upon their individual judgment, unsupported by clearly demonstrable facts. They were more astute judges of men, with a larger comprehension of the strength and weakness of human nature and a wide sympathy. They were characterized by a certain boldness less seen to-day, and bred of the necessity of staking their reputations upon much less certain evidence. They seemed to have been broader-minded and rather more in touch with affairs other than those of medicine. Their devotion to the ideals of medicine he believed to have been more sound. Instead of being required to weigh probabilities we were to-day able to assort facts. Judgments of character had given place to assortments of data, and whereas the practitioner of a generation ago was profoundly influenced in his decisions, by his study of the individual, the consultant of to-day might almost arrive at his opinion without ever seeing the patient. The amount of technical knowledge required of the physician to-day was enormously greater than was required of his predecessor, and it could not successfully be denied that he was far more likely to arrive at a just appreciation of the facts. With this advance had gone the necessary division of medicine into specialties, a division which the rapid accumulation of knowledge had rendered inevitable, and this had sounded the death knell of the general practitioner. His place had been taken, or rather was occupied, by the medical group, an aggregation or conglomeration of specialists who, having pooled the results of their investigations, were able with greater accuracy to come to a diagnosis. These groups had developed either around the hospital as a center or around some individual, who finding that medicine was passing away from him, had surrounded himself with assistants and associates equipped with special knowledge. Almost every internist or surgeon of large practice was in fact the head of a group, only it was unorganized and unnecessarily extensive. Each had an aurist, an oculist, an orthopedist, a dentist, a Roentgenologist, a chemist, a pathologist, a serologist, who examined his patients and on whose selective opinions, his own diagnosis, prognosis, and treatment must rest.

Some Medical Problems.—Dr. F. T. MURPHY of St. Louis directed attention to the hospitals, and advocated the proper training of the medical student, and said the true functions of the hospital were to render aid to patients, to advance science, and to teach students. The record of scientific development was a proud one. Small clouds which at times appeared upon the horizon did not necessarily mean a storm. Conspicuous evidence of selfishness in the profession, be this evidenced by individuals or groups, did not mean that the ideals of the past were being lost, but such clouds might be potential tempests. Even their appearance behooved us to strive for conscience as eagerly as we strove for scientific knowledge.

Typhus Fever.—Dr. RICHARD P. STRONG of Boston said the great epidemic of the black death, which caused the unprecedented mortality of one-fourth of the population of the earth, appeared in Europe about 1348, after devastating Asia and Africa. From a focus in the Crimea it spread by Turkey, Greece, and Italy, northward and westward over the whole of Europe, also attacking it from a second focus by way of Austria. It broke out anew at intervals up to the seventeenth century. Sweeping everything before it, this terrible plague brought panic and confusion in its train, and was said to have broken down all restrictions of morality, decency, and humanity. The epidemic of this disease which recently raged in Serbia, as had been intimated, was the most severe one which had occurred in modern times. A few cases of typhus had occurred in Serbia in October, 1914, but the disease did not make its appearance in epidemic form until January, 1915, and then in the northwestern part of the country, among the Austrian prisoners who were greatly crowded and who necessarily were compelled to live under very insanitary conditions. The disease quickly spread from them to other individuals and as the infected patients and the districts in which they were situated were not quarantined, and the Austrian prisoners and infected individuals were sent or allowed to go to various parts of the country, Serbia was soon afflicted with a terrible and widespread epidemic. The country, weakened by war, was not prepared for an epidemic, and for a time one might say that the typhus raged almost at will. The majority of the small number of Serbian doctors sooner or later became afflicted with the disease. Those who remained well were occupied with treating the sick and also the wounded from the battlefields, and methods for prevention were impracticable or were not undertaken. Wounded soldiers or those afflicted with minor ailments or diseases with relapsing fever, wandered into the hospitals at will and entered the wards filled with cases of typhus, sometimes occupying the same bed, for it was not unusual for two or even three patients to be found lying in the same bed, and the available floor space was also filled with patients with no beds. The epidemic increased through January, rose more rapidly in February and March, and reached its height in April when the number of cases was in the neighborhood of nine thousand per day. These figures were only approximate, for when he reached Serbia in April, there were no available statistics of the number of cases or deaths in the various cities, and only the approximate number of cases present in the military hospitals known. The American Red Cros, in addition to the hospital units it had already sent for Serbian relief work, decided to organize and send a sanitary commission for the purpose of combating the disease. The Rockefeller Foundation, from the first, was interested in this commission and generously supported it in conjunction with our Red Cross. Great Britain, France, and Russia also recognized largely from a military standpoint the extreme gravity of the epidemic and the frightful ravages caused by it and quickly organized, equipped and sent expeditions for checking it. Largely through the combined efforts of all these workers, and with the cooperation of the Serbian physicians and officials, the epidemic rapidly declined and for the last three weeks before his departure from Serbia they could not find a single fresh case of typhus. The sanitary condition of the army and the people was then excellent. He trusted that the sanitary demonstrations in the prevention of typhus, which had been given the Serbian people, and the construction of the various

disinfecting plants throughout the country would prevent the recurrence of another epidemic such as they had just witnessed, and which destroyed in the neighborhood of 150,000 people. All of the Serbian hospitals had been thoroughly disinfected before he left that country, and were ready for the reception of the wounded.

A Consideration of Gastric and Duodenal Ulcer from the Standpoint of the Internist.—Dr. W. F. Boggess of Louisville said he would urge that the internist be more careful and painstaking in his examination of the various digestive disturbances that came to him, to fit himself to recognize these conditions in their earlier stages, and to urge upon him the fact that there was a medical side to the question, and that if the majority of these patients went to the surgeon it was a reflection both upon the internist's diagnostic as well as therapeutic acumen. When did these cases cease to be medical and become surgical? In answer he would say that no time limit could be stated. Each case was an individual one. Not in two weeks, nor in six weeks, nor even in six months, if the patient was holding his own, could one feel that medical means had been entirely exhausted or had proven futile. Certainly not surgical when the patient was symptomatically and comfortably well, nor when the patient showed no signs or symptoms of pyloric stenosis. Nor when nourishment and nutrition had not proved impossible. But when all medical means had been intelligently tried, and patient threatened with a condition of chronic invalidism, and threatened emaciation, then one should call a surgeon with the assurance that he could and would take the case out of chronic invalidism and restore it to a fair, if not perfect, condition of health and happiness.

The Etiological Relationship between Gastric Ulcer and Gastric Cancer.—Dr. Frank Smithies of Chicago said that review was made of certain phases suggested by the study of 921 operatively and pathologically demonstrated cases of gastric ulcer and of 500 similarly proved instances of benign, peptic ulcer. Particular attention had been paid to the search for actual facts demonstrating the existence of an etiological relationship between gastric cancer and gastric ulcer. It seems to have been shown that benign gastric ulcer could be produced in a multitude of ways, the method of production having but relative effect upon the ulcer resulting, pathologically. It seemed that in a given gastric ulcer it was impossible to prognose its course, duration or type of termination. There were no experimental, clinical, or pathological data that absolutely demonstrated the mechanism of the malignant transition of benign gastric ulcer. This problem would apparently remain unsolved until the exact nature of the mechanism of malignant processes in general was determined. Clinically, the histories of instances of gastric cancer strongly suggested that such neoplasm arose most frequently from chronic, calloused gastric ulcer, clinically benign. It would appear that clinically it was impossible to segregate that group of chronic gastric ulcers which would undergo change to cancers from that which would continue as self-limited, benign processes. On account of the uncertainty in this regard, free excision of all chronic gastric ulcers should be performed whenever such procedure was mechanically possible. That this was a most important feature of cancer prophylaxis was proved by the fact that when gastric cancer could be definitely diagnosed, clinically and macroscopically, at laparotomy, hope of radical cure was slight. The knowledge of the foregoing facts imposed a moral responsibility upon internists and surgeons with respect both to the individual patient and the human family.

Dr. Charles G. Lucas of Louisville said as to the time factor, none of us was competent to give a statement as to when an ulcer might become malignant nor how long it would continue. He had in mind a patient who had a tumor of six months standing before seeking consultation. A laparotomy was done and the tumor was found to be inoperable. Patients with ulcer of the stomach should be placed in bed as soon as they came under the care of the internist, and they should then be carefully treated from four to five weeks. They should report often and submit to frequent examination. If, after six or seven weeks of effort of this kind, no results were obtained, then a surgeon should be called. These cases should be treated by both internist and the surgeon working together, and finally they should come back to the internist.

Dr. Willard J. Stone of Toledo, Ohio, said he would like to ask Dr. Smithies what percentage of gastric ulcer and duodenal ulcer in his experience showed a positive Wassermann reaction.

Dr. Chauncey Dowden of Louisville said that so far, we knew practically nothing as to the etiology of gastric and duodenal ulcer; hence it followed that our methods of treatment were more or less imperfect at the present time. If conditions incidental to appendicitis caused ulcer, then obstipation and constipation became important etiological factors. If appendicitis would cause gastric ulcer, why would not chronic obstipation bring about a like condition? In his opinion it might even produce pyloric spasm. We also had a condition which would in time cause gastric ulcer. He would like to impress upon the internist the importance of treating the ulcer patient before the condition became an ulcer. The majority of patients who came to us showing a condition of hyperacidity were in all probability ulcer patients. This was the time when they needed proper attention and, in all probability, the right treatment administered at this time would prevent the developmnt of duodenal or gastric ulcer.

Dr. Smithies, in closing, said in answering Dr. Stone's question, in his proved ulcer cases, the ratio of positive Wassermanns was 1 to 300. One of the first points in the cure of disease was to remove all the foci of infection, not only in the mouth, throat, and nose, but we should look out for an infected appendix or an infected gall-bladder. If we let these organs pass by unnoticed we were simply locking the door after the horse had escaped.

Breast Feeding.—Dr. J. Ross Snyder of Birmingham, Alabama, said he would suggest that medical associations throughout the country start an agitation to have midwives supplied for distribution with concise, accurate, and practical printed instructions to lactating mothers. Such an agitation would result in three-fold good. A large number of mothers would be directly helped; it would on account of their curiosity and their desire for advancement educate many midwives to greater usefulness, and last, but not least, it would bring to a realization of their own deficiencies a considerable number of doctors taking part in the agitation.

The Heart and Bleod Vessels in Tuberculosis.—Dr. Francis M. Pottenger of Monrovia, Cal., stated that tuberculosis might affect the blood vessels either from within or without, and the lesion might be of all degrees of severity from that of very slight trauma to necrosis. Sometimes an infection was followed by an opening in the vessel wall and hemorrhage; at other times an exudation resulted which went on to repair; and again an endarteritis with obliteration of the lumen occurred. It seemed probable that many of the hemorrhages which we had in tuberculosis, particularly those where only small amounts of blood were expectorated, might be due to the injury of the vessels resulting from action of toxins. Bacilli invaded the endothelial cells gave off toxins which attracted leucocytes and thus formed tubercles in the walls of the vessels. Miliary tuberculosis was a tuberculosis of the blood vessels in which many bacilli had escaped into the blood stream and found lodgment in vessels of the same tissue. It was from just such lesions as those here described that the bacilli which produced acute miliary tuberculosis came. The capillaries were most commonly affected, while small veins and arteries were less commonly so. Tubercles might be found in the walls of any vessels of the body, including the aorta. This being true, it was surprising that miliary tuberculosis was not a more common infection than it was. That it was not, was probably due to the fact that the vessel was often occluded by the inflammatory process so that bacilli did not get into the blood stream, and secondarily that protective cell sensitization and antibodies reduced the virulence of or destroyed the bacilli which gained entrance to the blood stream before they found lodgment in the tissues, in those patients in whom infection had been present long enough to build up a specific immunity. For the heart muscle itself he had great confidence in the use of digitalis and citrate of caffeine. If the early symptoms mentioned above were recognized and the patient was put in the recumbent position and given digitalis in proper doses, the crisis could often be averted. Digitalis strengthened the heart's contractions and in this way probably afforded better nutrition to the organ; but, whether this was the explanation or not, he had great confidence in its use. If digitalis was to be

used, it should be used in doses sufficiently large to produce an effect. He used a standardized tincture in doses of 10 to 15 minims three times a day until the pulse improved or the physiological effect was reached. This was generally shown by a nausea or irregularity of the heart. He then discontinued the remedy for three days and then repeated it again, giving the remedy three or four days and then withholding it for a like period. If the case was urgent, he often gave digalen intravenously in 15-minim doses three times a day until the effect was produced. Citrate of caffeine could be given in 3-grain doses every four hours and continued as long as necessary. The patient should be fed nourishing food in concentrated form. The bowels should be kept free to relieve any toxins that could be removed through the alimentary canal. The important thing in the handling of these cases was to recognize them early, and to treat them properly. These degenerative changes in the heart muscle might threaten the patient's life and yet the heart might recover itself as the patient improved.

Cardiac Anatomy and Pathology from the Roentgen Standpoint.—Dr. P. M. HICKEY of Detroit said if the Roentgen tube be placed at only a comparatively slight distance, say eighteen inches from the plate, it would follow that the distortion of the shadow cast by the heart would be considerable. Accordingly, some years ago two methods were proposed: First, orthodiagraphy by which parallel rays were employed, and, second, where the same result was secured by placing the tube at such a distance from the plate that the rays coming from the tube were practically parallel. Such a distance, it was assumed for some time, should be about 80 inches. This procedure, where the distance of the tube from the plate was extreme, was called by Alban Kohler teleoroentgenography. The disadvantages of this latter procedure were, inasmuch as the time of exposure increased with the square of the distance, that the strain upon the tube was considerable. During the past year, the writer had made comparisons of plates made with a tube distance of 36 inches in comparison with the plates of the same patient with a tube distance of 60 inches and found that one could practically see no difference in the size of the heart with the plate made at 36 inches. This statement applied to plates made with the tube behind the patient and the plate placed against the anterior chest wall. Where the tube was placed in front of the patient and the plate was against the back of the patient, slight distortion would be found. However, in general, he would state that plates made with the tube distance of 36 to 40 inches and the plate placed against the anterior wall of the chest were very satisfying for studying the comparative size, contour and position of the heart.

Spasmophilia.—Dr. J. P. SEDGWICK of Minneapolis stated that from 40 tabulated cases from private and consultation practice, in addition to the children in the University Clinics to whom calcium was given, he felt warranted in drawing the following conclusions: (1) In the acute and subacute cases under one year, with high electrical reactions, the results obtained with large doses of calcium chlorid were brilliant. (2) In the more chronic and very severe cases, as well as with the older children, calcium was of definite value. He had also used the magnesium sulphate injection treatment as advised by Behrend. This consisted in the subcutaneous injection of 20 c.c. of a ⅛ per cent. solution of magnesium sulphate. The results with this method had also been satisfactory, but the injections were painful and frightened the older children. The electrical reactions gave us a means of diagnosing this condition, whether active or latent, thus distinguishing it in its various manifestations, such as the convulsions from epilepsy and the laryngospasm from inflammatory croup. Laryngospasm, general convulsions, tetany in children, spasmodic apnea, the Chvostek and Trousseau phenomena were manifestations of the same diathesis or condition. The condition was closely related to some metabolic disturbance, probably of the calcium salts, and was markedly benefited by a carbohydrate, cow's milk free, or a breast milk diet. Phosphorus and cod-liver oil were of value by the effect on the calcium retention. Calcium and magnesium gave quicker and more definite results. The prognosis was usually good in the cases in which treatment was begun early.

Some Features in the Management of Surgical Disorders of Digestion.—Dr. W. D. HAINES of Cincinnati said the last phase in considering the management of the surgical disorders of digestion arising from the stomach itself, comprised the prevention of cancer. One-third of all cancers occurring in man were located in the stomach and the vast majority of these neoplasms originated in the margin of an unhealed gastric ulcer. He who recognized this clinical dictum and dealt radically with gastric ulcer ere malignancy had begun would prevent untold misery and suffering and add much to the sum of human life and happiness.

The Diagnosis of Renal Infections: An Analytical Study of 182 Cases.—Dr. JOHN R. CAULK of St. Louis said that out of 182 cases only 17.7 per cent. appeared with a diagnosis of kidney disease, and this would be much lower if it were not for the high percentage of positives in perinephritic abscess and calculus. It was quite striking that not a single case of pyonephrosis came in with a diagnosis of renal infection, and it was confused with malaria in a high percentage of cases. The average duration of symptoms in this series had been three years and six months, so long in many cases as to deprive the individual of satisfactory chances of recovery. Renal pain was present in 40.9 per cent., was most common in pyonephrosis and nephrolithiasis, about 70 per cent., and least common in tuberculosis, 17.6 per cent. Fever was present in 15.7 per cent. As to faulty diagnosis, appendicitis appeared in 6.6 per cent. of all the cases; most commonly confused with nephrolithiasis, 26.5 per cent.; 6½ per cent. in pyelitis. It was not confused with pyelonephritis, pyonephrosis, or tuberculosis. Bladder trouble was diagnosed in 60 per cent. of all cases, most common in tuberculosis, 93 per cent., and least in nephrolithiasis, 30 per cent. Pus was present in 93 per cent., casts in 7 per cent., most of these in pyelonephritis, 35 per cent. The general average was extremely low. Red blood cells in 25.1 per cent. Only 9.8 per cent. of these had gross bleeding. As to organisms present, the pure colon bacillus was found in 57 per cent. of the cases; 23.5 per cent. staphylococcus; 17½ per cent. mixed. Tuberculosis was present in 9.4 per cent. of all the cases. The functional test was diminished in 68.7 per cent. of the cases. It showed its most marked diminution in pyonephrosis, and its slightest in pyelitis. The *x*-ray was positive in 30.4 per cent. of all cases. Cystoscopic examination showed changes in the bladder wall in 58.9 per cent.

Mechanics of Renal Infection.—Dr. EDWARD L. KEYES of New York City said renal colic was an acute stoppage of the ureter, the cause of which was usually a small stone or a slight kink. Upon being called to such a case, we should immediately administer morphine to the point of relieving pain, not only for the purpose of consoling the sufferer, but also for the purpose of curing the condition, for if we could relieve the pain, and thereby relax the spasm, we actually relieved the retention, and permitted the unfolding of the kink for the passage of urine about the stone, or even the passage of the stone itself. In the second place, we had here a clue to the mystery that surrounded irrigation of the renal pelvis. Much of the benefit attributed to this treatment was undoubtedly due to the passage of the ureteral catheter, for it was to be noted that many cures attributed to this treatment followed the first or the second washing. Such cures were due to mechanical relief of slight obstructions. He had several times relieved acute renal infection by ureteral catheterization, and Dr. Howard Lilienthal some years ago recorded several striking illustrations of the therapeutic effect of ureteral catheterization in acute renal infection.

Orthopedic Treatment during the Period of Spontaneous Improvement after Infantile Paralysis.—Dr. H WINNETT ORR of Lincoln, Neb., stated that infantile paralysis was due to partial or complete destruction of the motor cells and peripheral nerves. This paralysis, so far as the nerve supply of any muscle or set of muscles was concerned, was usually temporary. This was for two reasons, first because the motor cells for any muscle or muscle group lay at different levels of the cord and were rarely all involved, and second, because many of those actually involved recovered. Permanent paralysis of any set of muscles was usually due to the fact that such muscles had been permitted to be overstretched by the contraction of unparalyzed opponents or by weight bearing without protection to such an extent that they would not respond to stimuli when the nerve elements regenerated. Mechanical protection of the muscles in the affected area against overstretching was the factor of first importance in treatment following the acute attack. He formulated the

following conclusions: (1) It was a serious fault to use electricity, exercises, or massage, or in fact almost any other treatment than careful splinting during the inflammatory or painful stage of infantile paralysis. (2) No treatment following the acute attack was complete or adequate unless it was accompanied by splints or apparatus to fully protect and relax the muscles involved. (3) It was a serious mistake to put any patient on his feet during the first year after the acute attack unless he was fully protected by splints or apparatus against deformity on account of paralyzed muscles or muscle groups. (4) The problem of getting the maximum of recovery during the first year after infantile paralysis was about 50 per cent. spontaneous improvement and somewhere between 25 and 50 per cent. more splinting and apparatus. (5) Finally, orthopedic writers had not succeeded in conveying to the profession at large, satisfactory information as to the proper relationship of the different therapeutic agencies appropriate after infantile paralysis.

Tendon Transplantation in Infantile Paralysis.—Dr. ALBERT H. FREIBERG of Cincinnati said operations for infantile paralysis had in the past been too complicated or had been so planned as to violate the laws of muscle mechanics. He found himself in accord with Stoffel in determining that: (1) The transplant must bear a fairly close morphological and functional relationship to the muscle whose function it was to supplant. (2) In order to possess effective contracility the transplant must be fastened to its new point of insertion under physiological tension only. (3) The transplanted muscle must not be used to hold the limb in a corrected position. In consequence of simplifying the operations much more might be expected in functional efficiency and uniformity of results. Emphasis was laid upon the advisability of proceeding to construct plans for operations only after the paralyzed muscles had had adequate mechanical support and local therapy. Most patients came for operation without this. Electricity was condemned because it had not been proved that it was of real therapeutic value and because its use did harm by being made a substitute for measures which were purposeful. If the local condition of the muscles was not thoroughly understood, unnecessary and unsuitable operations were likely to be done.

Prolapse of Bladder and Uterus.—Dr. THOMAS J. WATKINS of Chicago stated that the pathological changes in the part of the bladder wall which was attached to the vaginal wall had not received sufficient attention. These changes were due to stretching of this part of the bladder wall and produced vesical symptoms. The urethra was usually displaced downward and disturbed continence of urine. The pathological changes in the uterus resulted mostly from circulatory disturbances, such as congestion, edema, varices and hyperplasia. The following operations were advised, the choice depending upon the amount of prolapse, and the age of the patient as regards future pregnancies: (1) An advancement operation. (2) Fixation of the round ligaments to the anterior vaginal wall and fascia. (3) The transposition operation, transporting the relative position of the bladder and uterus. This was also called the interposition operation. Partial excision or amputation of the cervix was done with all of these operations as might be indicated and a perineorrhaphy was made. The advancement operation was valuable as it was well adapted for the cure of many cases and was easily and safely performed. The operation consisted chiefly in advancing the vaginal wall, including the submucous connective tissue, upon the cervix. The redundant tissue was excised; the peritoneal cavity was not opened; the bladder was freely separated from the anterior vaginal wall and the cervix; purse-string sutures were passed through the vaginal wall, the fascia, the cervix, and out through the connective tissue and mucous membrane. These sutures were so placed that they restored the urethra to its normal location and closed the ring of the bladder hernia. This operation gave excellent results in cases of a moderate amount of prolapse and did not interfere with subsequent pregnancies. It should displace all anterior elytrorrhapies for reasons that must be obvious to all surgeons. Vaginal attachment of the round ligaments into the vaginal wall was done in conjunction with the advancement operation in cases with a greater amount of prolapse, during the child-bearing period, and in cases of retroposition of the uterus. The chief points in the technique were, in addition to the advancement operation, opening the peritoneal cavity; the purse-string sutures included generous loops of the round ligaments, and might include some of the anterior tissue of the broad ligaments. The transposition operation was the one of election after the menopause. The fundus of the uterus was attached to the connective tissue and vagina sufficiently low to make recurrence of the bladder hernia impossible. He had had no recurrence of cystocele after this operation which he had been doing for seventeen years. The uterus was never in obstruction in the vagina when so sutured. Modifications of the operation were given for cases of very large uterus and for cases of complete prolapse with a very small uterus. The cavities of the uterus and vagina might be completely closed in very extensive cases of prolapse in old women where there was no objection to occlusion of the vaginal canal.

THE COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Stated Meeting, Wednesday, October 6, 1915.

THE PRESIDENT, DR. JAMES C. WILSON, IN THE CHAIR.

Some Applications of Physical Chemistry to Problems in Medicine.—Dr. HENRY LEFFMANN said that under the term physical chemistry a vast and intricate science of molecular conditions and transformations had grown up beginning to throw light in many directions upon the problems presented by both living and non-living matter. He proposed to set forth in the paper in a plain manner a few of the data of physical chemistry bearing directly upon practical medicine. The science, he said, was abstruse, and the facts could only be treated in an elementary way. For the purposes of the paper he selected the two phenomena—"ionization" and the "colloidal state." The phenomena of ionization, it was explained, were concerned esepecially with the condition ordinarily called solution, the latter term being limited to fluids produced by association of substances, one of which was primarily a liquid. The term solution, the author said, had a much wider significance in physical chemistry, common glass being considered a solution, but this broad meaning was not applied in the paper. While until a few decades ago the liquids obtained in dissolving common sugar and common salt in water were designated "solutions," it was now known that the activity of the salt was materially increased, while the sugar suffered no such change. The sodium atoms of the salt had by the act of solution acquired a positive electrical charge, while the chlorine atoms had acquired a negative charge. The proportion of salt thus modified was dependent largely upon the mass of water present. The modification of a substance by which it acquired these electrical charges were termed "ionization"; the respectively positively and negatively charged elements were termed "ions." The importance of the change lay in the fact that the chemical activity of the substance and the pressure of the solution were much enhanced by it. It was found that the most potent ionizing liquid was water. Generally the degree of ionization was increased by dilution. Interesting explanations of well-known phenomena were now possible under these principles. Boric acid, while of the same type as nitric acid, was far less active, the difference being due to the fact that boric acid was but feebly ionized, while nitric acid was largely ionized. This applied also in the dilution of concentrated acetic and sulphuric acids. The application of the data of ionization to the interpretation of the action of medicines was complicated by the fact that living protoplasm and membranes had specific selective powers, and thus tests *in vitro* might mislead; for example: under given conditions mercuric nitrate ionized to a much greater extent than mercuric chloride, yet the latter was ordinarily more toxic. According to Höber this was due to the fact that the chloride was more soluble in the lipoid substances contained in the membranes, and thus was enabled to get into contact with the protoplasm of the cells. Important also was the influence of salts upon one another. Dr. Leffmann stated that it was far from being generally true that when a mixture of two or more substances showed no appreciable change of conditions such mixture would have the properties of all the ingredients. An instance was that a mixture of mercuric chloride and hydrocyanic acid was not equivalent to mercuric cyanide because the substances reacted in a different manner to the dissolving liquid. Inasmuch, however, as other solvents than water acted but feebly in ionizing it was not unlikely that an alcoholic solution of mercuric chloride

and hydrocyanic acid would have a closer equivalency to mercuric cyanide than a solution in water. The cyanides afforded several striking instances of the anomalous effects of mixtures, and this data would seem to point to the importance of simplification in prescriptions. The files of any drug store, it was said, would show most extraordinary mixtures violating the simple principles of pharmaceutical chemistry, and in this connection he questioned whether the method of the homeopathic school of medicine of administering several potent substances at intervals might not be commended to the regular school. The phenomena of reaction of salts to the solvent and to each other when associated in solution were said to have important applications to the so-called "mineral waters," and in this respect no class of waters showed more untrustworthiness than the so-called "lithia waters." Another point brought into prominence by the progress of physical chemistry was the influence of extremely fine division. From a consideration of this phase it followed that by dividing a material finely the facility of chemical action was greatly increased, and among other qualities conferred were constant self-agitation and easier passage through porous partitions. It was shown that medicines insoluble, or difficultly soluble in the fluids of the body should be administered in as fine powder as possible, and here again, should reason be given to the homeopathic school. Because manufacturing chemists did not always apply the highest principles of physical chemistry in their processes there were sometimes found in drug stores preparations of distinctly inferior quality. The initiative in the field of the physical chemistry of colloids was said to be due largely to Thomas Graham, an English chemist, who in 1861, published the results of experiments upon diffusion through membranes. He had found that when a mixture was made of two substances, one of which was crystallizable and the other not, the former would pass rapidly through the membrane while the other was held back. While Graham had divided substances into "crystalloids" and "colloids" it was now known that such classification of substances was not fundamental, that they were conditions only and that the same substance might assume both states. The crystalline condition was said to probably result when molecular attractions were allowed more opportunity of acting; the colloidal, when less opportunity was afforded. Hence, it was found that crystals were produced by the solidification of a substance from a liquid to a gaseous state; also, that the presence of a minute amount of a crystal of the substance in solution would materially promote the separation in crystalline form, acting as a nucleus for the operation of the molecular forces. Whatever might be the effect of uric acid when in the blood or deposited in the tissues, it formed a serious interference when separated in the crystalline form from the urine. Reference was made to experiments under the supervision of Dr. Martha Tracy at the Woman's Medical College of Pennsylvania which indicated that a full meat diet increased the acidity of the urine. If this were established, it would be an important point, for the principal danger from uric acid was in its separation in the crystalline form in some part of the genitourinary tract. Such separation was promoted by increased acidity, and if a minute crystal were deposited at any point it would act as a nucleus, bringing about further separation of uric acid and of other compounds held in unstable solution in the urine. The administration of alkalies for the prevention of this separation, it was pointed out, might lead to the precipitation of substances not soluble in alkaline urine. It was obvious, therefore, that a full meat diet might cause or aggravate uric acid troubles, although not increasing the output of the acid itself. Knowledge of the nature and properties of colloids, it was remarked, explained many physiological and pathological phenomena. Intimately connected with this field of chemistry was the subject of enzymes, which probably formed the connecting link of living with non-living matter, showing colloidal properties and possessing high powers of absorption. The problem of the cell, the author said, was largely a problem of physical chemistry, which latter might well be characterized by the description of politics which Mr. Pickwick gave to Count Smaltork, "A difficult study of no inconsiderable magnitude."

Dr. Solomon Solis-Cohen said that Dr. Leffmann's paper dealt with a subject of such magnitude that a certain degree of temerity was required on the part of him who would approach it, not being a professional chemist. In so far as the physicochemical reactions in the living body were the same as those of the laboratory the laboratory findings might be applied to the problems of biology, to physiology, to pathology, and to therapeutics. Regarding, however, the great and increasing number of outstanding biological problems of the day, the value of the unknown factor, the x or the x, y, z, was so great that one must hesitate. No stronger illustration in this connection he felt could be given than the researches of Fischer upon edema and nephritis, yet he felt that few clinicians or pathologists would accept without considerable reserve Fischer's far-reaching conclusions. In the treatment of albuminuria and of edema resulting from nephritis Fischer advocated the introduction into the blood of a concentrated (*i.e.* a hyperhemotonic) alkaline saline solution; suggesting one containing from 10 to 20 grams of crystallized sodium carbonate, and 10 to 30 grams of sodium chloride to the liter of water. This was from two to six times the concentration of the ordinary, so-called physiologic saline solutions. Fischer also rejects, it was said, osmosis as an adequate explanation of cytolytic and similar phenomena, and opposes as unscientific, the common practice of restricting the intake of sodium chloride in conditions of edema associated with nephritis. Of his methods many striking instances of success, also many failures, had been reported. No analysis yet made had given data whereby the conditions determining the success or failure could be exactly estimated. Dr. Cohen referred to the investigations of Wolfgang Pauli of the phenomenon of ionization and his deductions that: (1) The effect of salt upon a protein is made up in the main of the algebraic sum of the effects of the individual ions; (2) that anions and kations antagonize each other. He had found that sodium sulphocyanide tended to reduce blood pressure and to prevent deposition of calcium in the arterial walls, so that it could be used with good clinical results in cases of arteriosclerosis. He found also that sulphocyanides were even more active than iodides in favoring the formation of readily soluble protein compounds with the heavy metals, thus favoring elimination in cases of chronic poisoning. The whole subject, Dr. Cohen remarked, came under the head of ion-colloid reactions important to pathologist and therapeutist. Warning should be given that whereas sulphocyanide might be safely administered in doses up to 1 gram daily for sedative and analgesic, as well as for pressure lowering effect, yet any compound of the sulphocyanide ion with an ester would produce almost instant death, owing to the solubility of the cell-lipoids in esters. In further illustration was the theory of narcosis by lipoid solvent substances referred to by Dr. Leffmann. In the application of such studies as those of Dr. Fischer's it was important to bear in mind the modern definitions of acidity, alkalinity, and neutrality. In Pauli's experiments it seemed strange to read that nitrate and acetate were ions inhibitive of precipitation, when nitric acid and acetic acid were used to precipitate albumin out of urine. In acetic and nitric acids, however there were according to the modern view, hydrogen acetate and hydrogen nitrate. Hydrogen was the cation, and if arranged in Pauli's series, should be placed as the strongest of all precipitants when ionized. Thus too, it was found that acetic acid was a more delicate test for albumin than nitric acid, because the acetate ion seemed to have less inhibiting power than the nitrate ion.

Dr. Alfred Stengel regarded the subject of physical chemistry as difficult and abstruse and one which those not technically interested in chemistry and physics could hardly hope to master. The use of saline solutions were too often resorted to with the barest knowledge of the principles involved. The use of solutions of greater concentration than the solutions of the body, in whatever way administered, would not bring about desired results. A solution to be absorbed would better be below the concentration. The introduction of hypertonic solutions into the blood stream, as advised by some French clinicians, he regarded as a questionable procedure. An argument in favor of physicians being familiar with the new science of physical chemistry was seen in the work of bacteriologists in the employment of Fuller's earth in the combat against diphtheria and typhoid carriers. The reports of investigators in this line had opened up large fields for inspection of direct practical interest to physicians.

Dr. Thomas McCrae thought it behooved a clinician to tread warily in the discussion of the points presented by Dr. Leffmann. A danger to which many were exposed was that of picking up terms without having

learned their meaning and this was particularly apt to be done in the subject of physical chemistry in talking of "ions" and "ionization," of "colloids" and "crystalloids." Dr. Leffmann, however, had made the matter perfectly clear. He referred to the marked bearing of ionization upon the bodily activities; all were perhaps familiar with the fact that ionization and electrolysis were closely connected. Reference was made to the work of Rogers of giving hypertonic solutions in the treatment of Asiatic cholera in which the results had justified the treatment. With Dr. Stengel he emphasized the danger of introducing substances under the skin, one example being that of calcium lactate. Much in practical medicine was to be learned from physical chemistry. In speaking of colloids and crystalloids there should be clear conceptions of the matter dealt with and a consideration of the degree of cell activity due to difference in pressure. In clinical medicine this knowledge would in many instances lead to a much more rational therapeusis.

Dr. Joseph Sailer felt that the subject illustrated, first of all, the sympathetic quality of the medical profession in that it must take toll of all the sciences for the understanding of disease and the consequent welfare of the human race. With Dr. McCrae he deprecated the tendency to apply terms in therapeutics with which the worker was not fundamentally familiar. He cautioned against the application too readily of definite experimental findings to living tissue, since the physical chemistry of living tissue was not yet a very clear factor. The fundamental element in physics, in chemistry, possibly in the universe, was the atom, and until a clear idea of the structure of the atom were had, much progress in the solution of the problems under consideration could not be made. Nevertheless, the application of definite facts of physical chemistry was an exceedingly important matter, and these facts were to be tested by empiricism for the determination of their value.

Dr. Leffmann, in closing said the discussion had taken the direction he had hoped, the further development of instances of the application of physical chemistry. Care had been given to the interpretation of phenomena by physicochemical methods and criticisms had been made of the want of definiteness in certain directions. Each one knew how extensive were the amplifications of the sciences and how impossible to keep pace with more than one narrow specialty.

The Efficiency of a System of Clinical Records and Annual Report, Dependent upon a Standardized Nomenclature.—Dr. Joseph M. Spellissy presented this paper which was illustrated with lantern slides.

Pathological Society of Philadelphia.

At a stated meeting held October 28 Dr. Nathaniel Ginsburg exhibited the following specimens: a "Pseudomucinous Cyst of the Appendix." The specimen was obtained in the course of an operation for ruptured ectopic pregnancy. The appendix was greatly enlarged and filled with watery fluid. "*X*-ray Plates Showing Pathological Fracture of a Bone-cyst in the Radius of a Child." The patient was a child two years old suffering from a painful disability of the forearm, the nature of which was discovered only on radioscopic examination. "A Salivary Calculus in the Duct of the Submaxillary Gland." The patient was a young man who complained of pain near the angle of the jaw on one side, especially superinduced by the ingestion of acids, and attended with the appearance of a temporary swelling in the same situation. "Hypertrophic Stenosis of the Pylorus in an Infant." The characteristic type of vomiting made the diagnosis easy and posterior gastrojejunostomy was performed and in its failure to relieve the symptoms anterior gastrojojunostomy was later performed, but the patient was too debilitated and failed to recover. Dr. Ginsburg also made a report of a case in which gastrojejunostomy had been performed in an adult more than a year before for the relief of a duodenal ulcer. Recurrence of the symptoms led to a secondary operation, when it was found that the surgically created channel of communication had closed and become the seat of ulceration, which it was thought was due to irritation caused by buried silk sutures.

Dr. Alfred Gordon presented a specimen of "Pontocerebellar Tumor." The case was characterized by slight loss of power and diminished sensibility on one side of the face, slightly increased knee-jerk and slight impairment of hearing on the same side, with a negative Wassermann reaction. A diagnosis of cerobello-pontine angle being made, and the symptoms increasing in severity, a decompression operation was undertaken, with a great measure of relief. The improvement, however, was only temporary, and a fatal issue ensued. Post-mortem examination confirmed the clinical diagnosis and the new growth proved to be a round-celled sarcoma.

Dr. A. H. Hopkins presented a communication entitled, "Sugar-content of the Spinal Fluid in Meningitis and Other Diseases." It was found that in health the cerebrospinal fluid contains a lesser amount of sugar than the blood, while in cases of meningitis of varied kind the proportion of sugar in the spinal fluid is diminished, as it is also in cases of syphilis of the nervous system and of other forms of diseases as well, while it is increased in cases of diabetes.

Drs. H. H. Austin and S. S. Leopold presented a communication entitled, "Extraordinary Polymorphonuclear Leucocytosis in Typhoid Fever." They reported the case of a young man who came into the hospital on about the sixteenth day of the disease and presenting classical symptoms of typhoid fever, including a positive Widal reaction, together with typhoid bacilli in the blood and the urine. Cytological examination of the blood disclosed a distinct leucopenia, with an extraordinary reduction in the number of circulating polymorphonuclear cells—less than 100, together with an almost equally extraordinary increase in the number of small lymphocytes, namely, more than 7000 in the cubic millimeter. In the further progress of the case the number of polymorphonuclears gradually increased, while the number of lymphocytes gradually diminished. A differential count of the nucleated cells indicated that there was a preponderance of recently generated leucocytes in the blood.

Dr. O. H. Perry Pepper presented a communication entitled "Endothelial Phagocytosis in Pleural Exudate due to *Bacillus Typhosus*." He reported a case of typhoid fever in the course of which a pleural effusion was detected, serum from which contained typhoid bacilli and yielded a positive Widal reaction. The fluid contained also endothelial cells singly and in groups engulfing leucocytes and erythrocytes.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

West Virginia State Board of Health.

ANATOMY.

1. Describe the structures of the index finger and their relation to bone tissue.
2. Give the anatomy of the kidneys.
3. Describe the portal circulation.
4. Describe the spinal cord and give its relation to other tissues.
5. Describe Scarpa's triangle, naming the most important structures nearest it.
6. What is meant by the circle of Willis?
7. Describe fully the stomach.
8. Describe the peritoneum and name structures to which it is attached.
9. Name and give insertions and attachments of the muscles of the forearm.
10. Describe the bones of the foot and give their articulation.

PHYSIOLOGY AND HISTOLOGY.

1. Give the principal forms in which connective tissue occurs.
2. Give the histology of the spleen.
3. Describe in brief the histology of the kidney.
4. Give a brief description of the capillaries.
5. What are the fundamental groups of elementary tissue?
6. Give the function of the lymph glands.
7. What is the effect of respiration upon pulse and blood pressure?
8. Name and give function of the ferments of pancreatic juice.
9. Give function of the liver.
10. Give the conditions affecting body temperature.

CHEMISTRY AND MEDICAL JURISPRUDENCE.

1. Define chemistry, element, and molecular weight.
2. What is an acid, a base, a salt, a radical?

3. From what is iodine derived? Give symbol and atomic weight.
4. State difference between quantitative and qualitative analysis.
5. Describe the chemical changes in olive oil in the alimentary canal.
6. What is your opinion of the physician's legal responsibility?
7. What is an ordinary witness? An expert witness?
8. What is molecular death? Somatic death?
9. Name some of the ways of identifying a dead body.
10. Under what conditions would a physician be justified in producing abortion? What precautions for self protection?

MATERIA MEDICA.

1. Give rules for giving medicine to children.
2. Salol—give composition, dose, and physiological action.
3. Name three hypnotics, give doses, and state which hypnotic is safest and why.
4. Salvarsan—give method of administration and name some of its dangers.
5. Serums and vaccines—name two of each, give doses and method of use.
6. Oleum ricini—give therapy.
7. Hydrotherapy—give indications.
8. Urotropin—give therapy.
9. Mercury—give preparations and therapy.
10. Cocaine—give therapy.

ANSWERS.

ANATOMY.

1. The *index finger consists of the following structures*, beginning with the skin on the palmar surface: Skin, subcutaneous tissue and fat, the sheath of the flexor sublimis digitorum, flexor sublimis digitorum, and flexor profundus digitorum, branches of the digital arteries and nerves (from radial artery and median nerves), and the three phalanges. Behind, will be found the extensor communis digitorum and the extensor indicis, with expansions of the first lumbrical and first dorsal interosseous muscles, branches of the second and third digital nerves (from the radial), subcutaneous tissue, and skin. The tendon of the flexor sublimis digitorum divides into two slips opposite the base of the first phalanx to allow of the passage of the flexor profundus digitorum. The joints between the phalanges are provided with a capsule and anterior and two lateral ligaments; these are found next to the bones.

2. The kidneys are situated in the back of the abdominal cavity, one on each side of the vertebral column, behind the peritoneum, and extending from the eleventh rib to the second or third lumbar vertebra. The right kidney is about half an inch lower than the left one. Each kidney is about four inches long, two inches broad, and one inch thick, and weighs about four and a half ounces. The kidneys are kept in place by their vessels, fatty tissue, and the peritoneum. The shape is characteristic. Each kidney is surmounted by the suprarenal gland, is surrounded by a capsule, and consists of a cortical and medullary portion. In the cortical portion are found the Malpighian corpuscles, which are tufts of capillaries, and are surrounded by a capsule which is continuous with the uriniferous tubule which ends in the renal papilla.

Relations of the right kidney. In front: Right lobe of liver, second part of duodenum, hepatic flexure of colon (of which the last two areas are nonperitoneal). *Behind.* Diaphragm, quadratus lumborum, psoas, fascia covering these muscles, anterior lamella of lumbar aponeurosis, ilio-hypogastric ilio-inguinal, nerves, last dorsal; first lumbar artery, pleura, last intercostal space, and twelfth rib.

Relations of the left kidney. In front: Fundus of stomach, postero-internal surface of spleen, tail of pancreas, descending colon (of which last two are nonperitoneal). *Behind:* As on right, except that left kidney, lying rather higher, lies over 11th rib.

Above each kidney is the suprarenal body.

Below each kidney is the iliac crest.

3. By the *portal circulation* is meant the capillary circulation of venous blood in the liver, between the portal and hepatic veins.

Portal circulation: "The hepatic artery and the portal vein convey blood to the liver. The artery carries arterial blood, and the vein food-laden venous blood from the walls of the alimentary canal, and from the spleen and pancreas. Both vessels enter the liver at the transverse fissure, and they ramify in its interior, breaking up into small terminal branches which run between the lobules and send fine capillary branches into their substance; from these latter branches the blood passes into the capillary tributaries of the intralobular veins, thence to the sublobular veins, and from the sublobular veins to the hepatic veins, which terminate on the posterior surface of the liver in the inferior vena cava." (Bain's *Medical Practice.*)

4. "The *spinal cord* is the elongated portion of the cerebrospinal axis contained in the spinal canal. Its length is about sixteen to eighteen inches, extending from the medulla above to the lower border of the first lumbar vertebra below, where it terminates in the cauda equina by a slender prolongation of gray substance, called the conus medullaris. It presents two enlargements, the upper or cervical, extending from the third cervical to the second dorsal vertebra, and the lower about the position of the second or third dorsal vertebra. It is divided into two lateral halves by the anterior and posterior median fissures, united in the center by the commissure. The lateral portions are again subdivided by the antero-lateral and postero-lateral fissures into the anterior lateral and posterior lateral columns, and posteriorly a narrow fissure separates the posterior median column from the posterior median fissure. The gray substance occupies the center of the cord, and is arranged into two crescentic masses connected together by the gray commissure. The posterior horn forms the apex cornu, from which arises the posterior root of the spinal nerves. The anterior horn is thick and short, and affords origin to the anterior root of the nerves. The gray commissure contains throughout its whole length a minute canal the central canal, or ventricle of the cord, continuous above with the fourth ventricle." (Young's *Handbook of Anatomy*).

The relation of the structures in the vertebral column is (from without inward), the vertebra; venous plexus between the bone and the dura; the dura, arachnoid and pia with ligamenta denticulata; the cerebrospinal fluid; the spinal arteries and veins; the spinal cord.

5. Scarpa's triangle is a triangular area or depression situated just below the fold of the groin. It is bounded *above* by Poupart's ligament, *externally* by the Sartorius, and *internally* by the inner margin of the Adductor longus; its *apex* is formed by the junction of the Adductor longus and Sartorious. The *floor* is formed, from without inward, by the Iliacus, Psoas, Pectineus, Adductor brevis, and Adductor longus. *Contents:* The femoral vessels pass from about the center of the base to the apex, the artery being on the outer side of the vein; the artery gives off the superficial and profunda branches, and the vein receives the deep femoral and internal saphenous; the anterior crural nerve lies to the outer side of the femoral artery; the external cutaneous nerve is still further external, lying in the outer corner of the space; just to the outer side of the femoral artery, and in the sheath with it is the crural branch of the genitocrural nerve. At the apex, the vein (which at the base was internal to the artery) lies behind the artery. The triangle also contains fat and lymphatics.

6. The *circle of Willis* is an arterial anastomosis situated at the base of the brain. It is formed: In front by the two anterior cerebral arteries (branches of the internal carotid), which are connected by the anterior communicating artery; behind, by the two posterior cerebrals (branches of the basilar artery), which are connected to the internal carotid on each side by the posterior communicating artery.

7. The *stomach* is that pouch-like portion of the alimentary canal which is situated between the esophagus and the small intestine. It is conical, with base to left side; the upper border is concave, and is called the *lesser* curvature; the lower border is convex, and is named the *greater* curvature. The left extremity is known as the *fundus*, above and to the right of which is the *cardiac* orifice, and the right or small end is termed the *pyloric* extremity. It occupies left hypochrondriac and epigastric regions. Its *orifices are cardiac*, above, communicating with the esophagus; *pyloric*, at the right extremity, passing into the duodenum. It is 10 to 12 inches long, 4 to 5 inches in diameter at widest part. Its *left* or *cardiac end* is fixed by esophagus and gastrophrenic ligament to diaphragm, lying beneath the

seventh left costal cartilage, one inch from sternum; it is connected with the spleen by the gastrosplenic omentum. The *right* or *pyloric end* reaches the gall-bladder, touching under part of quadrate lobe of liver; is very movable; when stomach is empty is in midline four inches below tip of gladiolus. *Anterior surface*, which also looks upward, is in contact with, from left to right, diaphragm, abdominal parietes (epigastric region), under surface of liver. *Posterior surface* is separated from pancreas, crura of diphragm, aorta, vena cava inferior, and solar plexus, by lesser sac of peritoneum. *Superior border* is attached to liver by small omentum. *Inferior border* gives attachment to great omentum. *Coronary* and *pyloric* arteries run along lesser curvature; *right* and *left gastrocpiploic*, along inferior or greater curvature; *vasa brevia*, from the splenic to fundus. *Right pneumogastric* nerve supplies the posterior surface; *left pneumogastric*, the anterior surface; *sympathetic*, from the solar plexus, both surfaces. —(*Aids to Anatomy.*)

The Mucosa "is a pale, pinkish-ash color, thickened toward the pylorus, where it presents numerous rugæ, or pleats, and at the pyloric end it helps to form the pyloric valve. It is lined throughout with columnar epithelium, and is studded with three kinds of minute tubes, the gastric follicles, and lenticular glands. The gastric follicles consist of two kinds, the pyloric and the peptic glands, the former most abundant at the pyloric end and the latter distributed all over the surface of the stomach. The *pyloric* or *mucous glands* consist each of from two to four blind tubes opening into a common duct, and lined throughout by columnar epithelium. The *peptic glands* are similar in structure, but have a much shorter duct, and contain, in addition, peculiar large, spheroidal, granular *peptic cells*. The *lenticular* or *simple solitary glands* are small masses of lymphoid tissue scattered throughout the connective tissue framework of the stomach between the gastric follicles."—(Young's *Anatomy.*)

8. *Peritoneum. Course of, forming greater sac—in longitudinal section.*—"Passing down from the umbilicus, the peritoneum lines the anterior abdominal wall —covers the urachus and obliterated hypogastric arteries—passes onto the bladder, from its upper aspect to the trigone—is reflected onto the anterior and upper part of the lateral aspects of the rectum, in the male, forming the rectovesical pouch. In the female, the reflection is from the bladder onto the uterus (uterovesical fold)—extending thence over the upper portion of the posterior vaginal wall—and thence to the rectum (recto-vaginal pouch). From the rectum, the sigmoid flexure of the colon is entirely covered (sigmoid mesocolon)—the ascending and descending colons being covered, generally, only anteriorly and laterally—and passing from the spine downward, the peritoneum covers the small intestines, forming the lower leaf of the mesentery—and thence back again, completing the investment of the small bowel, forming the upper leaf of the mesentery—and passes backward over the transverse portion of the duodenum to the pancreas—thence forward to form the inferior layer of the transverse mesocolon—covers the inferior and part of the anterior aspect of the transverse colon—thence runs downward to form the posterior layer of the great omentum—returning to form the anterior layer of the great omentum—thence to the stomach, covering its antero-superior aspect—thence to the under surface of the liver, forming the anterior layer of the lesser or gastrohepatic omentum—thence covers the inferior surface of the liver, from the transverse fissure to its anterior border—whence it is reflected over the anterior border to cover the superior surface of the liver to the posterior peritoneal limit—thence it passes to the inferior concave surface of the diaphragm (superior layer of the coronary ligament)—thence over the anterior portion of the concavity of the diaphragm to the anterior abdominal wall—whence it passes down the anterior abdominal parietes to the umbilicus, to the place of beginning.

Course of the Peritoneum Forming the Lesser Sac—In Longitudinal Section.—"Beginning at the posterior aspect of the stomach, which it covers, the peritoneum of the lesser sac passes upward to the inferior surface of the liver, behind the transverse fissure, forming the posterior layer of the lesser or gastro-hepatic omentum—and having covered the postero-inferior aspect of the liver, it passes on to the under surface of the diaphragm (inferior layer of the coronary ligament)—thence passes downward over the posterior portion of the concavity of the diaphragm to the spine, covering the great vessels—thence to the pancreas—thence forward, forming the upper layer of the transverse mesocolon—covers the supero-anterior aspect of the transverse colon—descends, forming the innermost layer of the great omentum—then ascends to the greater curvature of the stomach—and covers its posterior wall, to the place of beginning. The lesser sac is in relation with the inner aspect of the spleen, forming the inner layer of the gastrosplenic omentum—and also in relation with the superior portion of the left kidney"—(Bickham's *Operative Surgery.*)

9. *Muscles of the forearm:* PRONATOR RADII TERES. *Origin:* Humerus, just above the internal condyle, and inner side of coronoid process of ulna. *Insertion:* Middle of outer surface of shaft of radius.

FLEXOR CARPI RADIALIS. *Origin:* Internal condyle of humerus. *Insertion:* Base of metacarpal bone of index and middle fingers.

PALMARIS LONGUS. *Origin:* Internal condyle of humerus. *Insertion:* Palmar fascia.

FLEXOR CARPI ULNARIS. *Origin:* Internal condyle of humerus, and olecranon and upper and posterior part of ulna. *Insertion:* Pisiform bone and annular ligament.

FLEXOR SUBLIMIS DIGITORUM. *Origin:* Internal condyle of humerus, coronoid process of ulna, and oblique line of radius. *Insertion:* Second phalanges of fingers.

FLEXOR PROFUNDUS DIGITORUM. *Origin:* Upper part of anterior and inner surfaces of shaft of ulna, and from coronoid process. *Insertion:* Last phalanges of fingers.

FLEXOR LONGUS POLLICIS. *Origin:* Anterior surface of shaft of radius, and coronoid process of ulna. *Insertion:* Last phalanx of thumb.

PRONATOR QUADRATUS. *Origin:* Lower part of anterior surface of ulna. *Insertion:* Lower fourth of anterior part of radius.

SUPINATOR LONGUS. *Origin:* Upper part of external supracondylar ridge of humerus. *Insertion:* Styloid process of radius.

EXTENSOR CARPI RADIALIS LONGIOR. *Origin:* Lower part of external supracondylar ridge of humerus. *Insertion:* Metacarpal bone of index finger.

EXTENSOR CARPI RADIALIS BREVIOR. *Origin:* External condyle of humerus, external lateral ligament of elbow-joint. *Insertion:* Metacarpal bone of middle finger.

EXTENSOR COMMUNIS DIGITORUM. *Origin:* External condyle of humerus. *Insertion:* Second and third phalanges of fingers.

EXTENSOR MINIMI DIGITI. *Origin:* External condyle of humerus. *Insertion:* Second and third phalanges of fingers.

EXTENSOR CARPI ULNARIS. *Origin:* External condyle of humerus, and posterior border of ulna. *Insertion:* Metacarpal bone of little finger.

ANCONEUS. *Origin:* External condyle of humerus. *Insertion:* Olecranon and upper and posterior part of shaft of ulna.

SUPINATOR RADII BREVIS. *Origin:* External condyle of humerus, external lateral ligament of elbow-joint, orbicular ligament, and from ridge of ulna. *Insertion:* Bicipital tuberosity and oblique line of radius.

EXTENSOR OSSIS METACARPI POLLICIS. *Origin:* Outer and posterior part of shaft of ulna, and middle of posterior surface of shaft of radius. *Insertion:* Base of metacarpal bone of thumb.

EXTENSOR BREVIS POLLICIS. *Origin:* Posterior surface of shaft of radius. *Insertion:* First phalanx of thumb.

EXTENSOR LONGUS POLLICIS. *Origin:* Outer and posterior part of shaft of ulna. *Insertion:* Last phalanx of thumb.

EXTENSOR INDICIS. *Origin:* Posterior surface of shaft of ulna. *Insertion:* Second and third phalanges of index finger.

10. *Bones of foot.*—Seven tarsal (os calcis, astragalus, cuboid, scaphoid, and internal, middle, and external cuneiform); five metatarsals; and fourteen phalanges.

ARTICULATIONS. *Os calcis:* Astragalus and cuboid.

Astragalus: Tibia, fibula, os calcis and scaphoid.

Cuboid: Os calcis, external cuneiform, fourth and fifth metatarsals, and (sometimes) scaphoid.

Scaphoid: Astragalus, three cuneiform, and (sometimes) cuboid.

Internal cuneiform: Scaphoid, middle cuneiform, first and second metatarsals.

Middle cuneiform: Scaphoid, internal and external cuneiform, and second metatarsal.

External cuneiform: Scaphoid, middle cuneiform, cuboid, and second, third, and fourth metatarsals.

First metatarsal: Internal cuneiform, second metatarsal, and first phalanx of great toe.

Second metatarsal: First metatarsal, internal cuneiform, middle cuneiform, external cuneiform, third metatarsal, and first phalanx of second toe.

Third metatarsal: Second metatarsal, external cuneiform, fourth metatarsal, and first phalanx of third toe.

Fourth metatarsal: Third metatarsal, external cuneiform, cuboid, fifth metatarsal, and first phalanx of fourth toe.

Fifth metatarsal: Fourth metatarsal, cuboid, and first phalanx of little toe.

Phalanges: The first row, with the metatarsals behind, and the second row of phalanges in front; the second row of the four outer toes, with the first and third phalanges; of the great toe, with the first phalanx; the third row of the four outer toes, with the second phalanges.

PHYSIOLOGY AND HISTOLOGY.

1. The *principal varieties of connective tissue* are: Areolar, adipose, elastic, fibrous, retiform, lymphoid, cartilage, and bone. They all serve to connect and support other tissues.

2. "The *spleen* is invested by a thick capsule, consisting of fibroelastic tissue and a large proportion of visceral muscle fibers. The capsule sends trabeculæ into the interior of the organ. These are thick, and the nuclei of the muscle fibers in them stand out conspicuously in stained specimens. The bulk of the organ is deep red in color, and is called the spleen pulp. In the pulp are numerous whitish nodules, about the size of a pin's head. These nodules are composed of lymphoid tissue surrounding small arteries, and are called Malpighian corpuscles. The pulp consists of a network of fine fibers, with a number of flattened and branched cells situated on the fibers and at their crossings. In the spaces between the fibers are numerous red corpuscles, large lymphocytes, and other blood cells. Many of the red corpuscles undergo disintegration in the large lymphocytes, so that pigment, both intracellular and free, is present. An occasional giant cell of bone marrow type is seen in the spleen pulp. The splenic artery breaks up at the hilus, and the branches pass into the interior of the organ along the trabeculæ. Passing away from the trabeculæ, their outer coat becomes surrounded at intervals by nodules of lymphoid tissue—the Malpighian corpuscles. Each corpuscle usually shows a germ center. The arteries open into capillaries, which, in turn, open into the interstices of the pulp. From the pulp spaces there open wide venous sinuses, which are encircled by fibers of the reticulum, and are lined by a very prominent endothelium. These sinuses open into the radicles of the splenic vein." (*Aids to Histology.*)

3. "The kidney is a compound, tubular gland composed of microscopic tubules whose function it is to secrete from the blood those waste products which collectively constitute the urine. If the apex of each pyramid be examined with a lens, it will present a number of small orifices, which are the beginning of the uriniferous tubules. From this point the tubules pass outward in a straight but somewhat divergent manner toward the cortex, giving off at acute angles a number of branches. From the apex to the base of the pyramids they are known as the tubules of Bellini. In the cortical portion of the kidney each tubule becomes enlarged and twisted, and after pursuing an extremely convoluted course, turns backward into the medullary portion for some distance, forming the descending limb of Henle's loop; it then turns upon itself, forming the ascending limb of the loop, reenters the cortex, again expands, and finally terminates in a spheric enlargement known as *Müller's* or *Bowman's capsule*. Within this capsule is contained a small tuft of blood-vessels, constituting the *glomerulus*, or *Malpighian corpuscle*. Each tubule consists of a basement membrane lined by epithelium cells throughout its entire extent. The tubule and its contained epithelium vary in shape and size in different parts of its course. The termination of the convoluted tube consists of a little sac or capsule, which is ovoid in shape and measures about 1/200 of an inch. This capsule is lined by a layer of flattened epithelial cells, which is also reflected over the surface of the glomerulus. During the periods of secretory activity the blood-vessels of the glomerulus become filled with blood, so that the cavity of the sac is almost obliterated; after secretory activity the blood-vessels contract and the sac-cavity becomes enlarged. In that portion of the tubule lying between the capsule and Henle's loop the epithelial cells are cuboid in shape; in Henle's loop they are flattened, while in the remainder of the tubule they are cuboid and columnar." (Brubaker's *Physiology.*)

4. "A *capillary* is a small vessel from 7 to 16 μ in diameter. Its wall consists of a single layer of endothelial cells. The cells are somewhat elongated in the long axis of the vessel. Their edges are serrated and are united by a small amount of intercellular substance which can be demonstrated by the silver nitrate stain. In certain capillaries those of the early embryo, of the kidney glomeruli, of the chorioid coat of the eye, of the liver, no cell boundaries can be made out. In these capillaries the endothelium appears to be of the nature of a syncytium. Capillaries branch without diminution in caliber, and these branches anastomose to form capillary networks, the meshes of which differ in size and shape in different tissues and organs. The largest meshed capillary networks are found in the serous membranes and in the muscles, while the smallest are found in the glands, as *e. g.* the liver. As to caliber, the largest are found in the liver, the smallest in muscles." (Bailey's *Histology.*)

5. The fundamental groups of elementary tissue are: Epithelial, Connective, Muscle and Nerve.

6. The *functions of the lymphatic glands and vessels* are: "(1) Mechanical, protective, or regulatory of the circulation, the serous surfaces, bursæ, tendon sheaths, the cerebrospinal fluid. (2) The absorption of digested products, the intestinal lymphatics or lacteals. (3) The formation of the blood in the thymus, bone marrow, spleen, and lymphatic glands. (4) The destruction of injurious materials in the spleen, lymphatic glands, and the lymphadenoid tissue of the respiratory tract, especially the nasopharyngeal section."—(Spencer and Gask's *Surgery.*)

7. The *pulse* is more frequent during inspiration and less frequent during expiration.

Blood-pressure rises a little with each inspiration and falls during expiration.

8. *Ferments of the pancreatic juice:* (1) *trypsin*, which changes proteids into proteoses and peptones, and afterward decomposes them into leucin and tyrosin; (2) *amylopsin*, which converts starch into maltose; (3) *steapsin*, which emulsifies and saponifies fats; and (4) a milk-curdling ferment. All of these act in an alkaline medium only.

9. The *functions of the liver* are: (1) the secretion of bile; (2) the formation and storage of glycogen; (3) the formation of urea and uric acid; (4) the manufacture of heat; (5) the formation of creatinine; (6) the production of antithrombin; (7) the conversion of poisonous and harmful into inert material; (8) it is also a reservoir for blood on its way to the heart.

10. The normal body temperature is *regulated* and *maintained* by the thermotactic centers in the brain and cord keeping an equilibrium between the heat gained or produced in the body and the heat lost.

Heat is produced in the body by: (1) Muscular action; (2) the action of the glands, chiefly of the liver; (3) the food and drink ingested; (4) the brain; (5) the heart; and (6) the thermogenetic centers in the brain, pons, medulla and spinal cord.

Heat is given off from the body by: (1) The skin, through evaporation, radiation, and conduction; (2) the expired air; (3) the excretions—urine and feces.

CHEMISTRY AND MEDICAL JURISPRUDENCE.

1. *Chemistry* is that branch of science which treats of the composition of bodies, their changes in composition, and the laws governing such changes. An *element* is a substance which cannot, by any known means, be split up into other, dissimilar, substances.

Molecular weight is the weight of a molecule of a substance as compared with the weight of an atom of hydrogen.

2. An *acid* is a compound of an electro-negative element or radical with hydrogen, part or all of which hydrogen it can part with in exchange for an electro-positive element, without the formation of a base.

A *base* is a ternary compound capable of entering into double decomposition with an acid to produce a salt and water.

A *salt* is a substance formed by the substitution of an electro-positive element for part or all of the replaceable hydrogen of an acid.

A *radical* is a group of atoms which can enter or leave a chemical reaction like a single atom.

3. Iodine is derived from sea-weed. Symbol, I; atomic weight, 127.

4. By *qualitative analysis* we determine what elements or groups of elements are present in a substance. By *quantitative analysis* we determine also the exact amounts of these elements or groups of elements.

5. Olive oil is partly emulsified, partly saponified in the intestines, its glycerin being set free and its fatty acids combining with the free alkalies to form soap, which with the emulsion forms the molecular basis of the chyle, entering the blood through the lacteals and being finally oxidized into carbon dioxide and water though an excess will appear unchanged in the urine. —(Potter's *Materia Medica.*)

6. A physician is not at all bound to accept a professional call; but if he accepts, he is bound to continue in attendance until the patient no longer requires his services, or he is discharged. He can leave during the continuance of the condition for which he was called only after giving ample notice of his intention to discontinue his services, and allowing a reasonable time for the patient to obtain the services of another physician.

The physician undertakes to use proper skill, care, and judgment in diagnosing and treating the case, and also to give full instructions as to how the patient may be best cared for. The physician is not allowed to divulge anything that he learned while in professional attendance, provided such knowledge was necessary to the successful conduct of the case.

Malpractice is a failure on the part of a medical practitioner to use such skill, care, and judgment in the treatment of a patient as the law requires; and thereby the patient suffers damage. If due to negligence only, it is *civil* malpractice. But if done deliberately, or wrongfully, or if gross carelessness or neglect have been shown, or if some illegal operation (such as criminal abortion) be performed, it is *criminal malpractice.*

7. An *expert* witness may give his *opinion* on facts or supposed facts as noted by himself or asserted by others. *Theoretically*, this can only be done by one perfectly familiar with the subject in question; but *practically* any (or almost any) physician with a license to practise is accepted as an expert witness. A *non-expert* witness testifies only the *facts* which he has seen, or heard, or with which he has become acquainted by personal observation.

8. *Molecular death* is caries, or death of some cells. *Somatic death* is death of the entire body.

9. "When a body entirely unknown is found, the decision as to identity may be simplified by exclusion, so that such general questions as those of sex, race, age, height, and weight, are first settled; then with the help of the clothing, vocational stigmata, and the circumstances under which the body is found, much may be learned as to the individual and the class of life from which he came. The color, amount, and character of hair, color of eyes, the condition and number of the teeth, and general type of features, the presence of deformities, tattoo marks, and cicatrices, will, in the entire and fresh, unmutilated body, give us a basis on which to rest a thorough and complete identification. It frequently happens, however, that bodies of unknown dead are found after the lapse of days or weeks, or, when found in water or in the woods, may be so disfigured as to make useless most of those means of identification which are most commonly used. In such instances one makes the most of those points which are at his command. When from decomposition, or for other reasons, it becomes necessary to bury or in other ways dispose of the body before identification is complete, proper photographs should be taken, and the contents of the pockets, and other possessions found on or about the body, which may assist in identification, should be retained for future reference."—(Dwight's *Medical Jurisprudence.*)

10. Conditions that justify the induction of premature labor: (1) Certain pelvic deformities; (2) placenta prævia; (3) pernicious anemia; (4) toxemia of pregnancy; (5) habitual death of a fetus toward the end of pregnancy; (6) hydatidiform mole; (7) habitually large fetal head.

The physician should protect himself by calling in consultation another reputable physician of recognized standing.

MATERIA MEDICA.

1. *Rules for giving medicine to children:* "Never prescribe a drug without a good and sufficient reason. Prescribe so that the dose will be small in amount and as agreeable as possible. Pills and capsules are not intended for children who rarely can swallow them. Prescriptions should be simple and if possible contain but one or at most two drugs. Powders made up with sugar of milk are mixed with water and given from the teaspoon. Tablet triturates form an easy and accurate method of giving drugs (except nitroglycerin). If the child is unwilling, the medication on the spoon is quickly slipped on to the tongue and the spoon held in position well back until swallowing takes place. In this way the child cannot regurgitate it. Begin with small doses in early life and increase if the desired effect is not obtained. Heroic doses, however, may be used in emergencies where rapid and active stimulation is required. Hypodermatic injection of the stimulant is often required to produce physiological effects. The rule that an infant up to a year should receive one-twentieth of, and at one year one-tenth of the adult dose, is to be followed in the majority of cases. The stimulants, however, are exceptions to this rule. At the fifth year one-fifth, and about the tenth year one-half the adult dosage is usually to be given."—(Chapin and Pisek's *Diseases of Children.*)

To determine the proper dosage for a child: Let x = the age of the patient; then $\frac{x}{x+12}$ = the fraction of the adult dose which the patient should receive. Thus, a patient four years old should receive $\frac{4}{4+12} = \frac{4}{16} = \frac{1}{4}$ of an adult dose.

2. *Salol* is phenyl salicylate; and is composed of 60 parts of salicylic acid, and 40 of carbolic acid. Dose, gr. vijss. Its *physiological action* is: antiseptic, antipyretic, and germicidal. Care should be exercised in its administration, because in the small intestine it is decomposed into its constituent parts, and symptoms of carbolic acid poisoning may develop.

3. *Three important hypnotics:* (1) Chloral hydrate; dose, gr. xv to xx. (2) Sulphonal; dose, gr. xv to xxv. (3) Trional; dose, gr. xv to xxv.

Indications: They are all used to produce sleep (when no pain is present).

Chloral hydrate produces a natural sleep, acts promptly, but is of no service if pain is present; it also lowers the body temperature. It can be given for a long time without deleterious effect, but it may irritate the tissues and weaken the heart.

Sulphonal produces a natural sleep, but is of slow action, requiring 3 or 4 hours to take effect; it is of no use if pain is present, does not irritate the tissues and weaken the heart, but is probably not so good for continuous use as chloral hydrate, though the two may replace each other for a time.

Trional is very similar to sulphonal but is more soluble, and acts quicker. Both sulphonal and trional are supposed to be safer than chloral.

Sulphonal is said to be safer than trional because it contains fewer ethyl groups than the latter does.

4. SALVARSAN. "It has become the regular custom to administer salvarsan *intravenously*, because in a number of instances its *intramuscular* injection was followed by necrosis and the formation of an abscess, the arsenic remaining unabsorbed. A number of deaths have occurred from its use. The untoward effects are: (1) The Jarisch-Herxheimer reaction, in which the secondary eruption becomes darker and appears to spread for a number of hours. It is believed to be the result of insufficient dosage at the outset. (2) Irritation of the tissues, with lymphangitis, from leakage in the neighborhood of the vein.

After effects.—The usual ones are headache, nausea, malaise, lasting from twelve to twenty-four hours.—(Bastedo's *Materia Medica.*)

5. *Antidiphtheritic serum*, immunizing dose 500 units, curative dose 3,000 units; it is injected subcutaneously.

Antitetanic serum, dose 2½ to 5 drams; it is injected into the spinal cord.

Typhoid vaccine, dose 500 to 1,000 million for first dose, double this amount for second, and third doses; given hypodermatically.

Streptococcus vaccine, dose 10 to 25 million, hypodermatically.

6. COD LIVER OIL is a demulcent and emollient; it is a tissue food. It is used in tuberculosis, rheumatism, strumous diseases, rickets, nervous diseases, and wasting diseases of childhood.

7. HYDROTHERAPY. "*Cold water* or *ice* has many external applications of value in the treatment of dis-

ease. As a wet pack it is used in tonsillitis, diphtheria, and croup. Cold baths are the most effective antipyretic in the high temperature of fevers, and the cold wet pack is used for the same purpose. Ice or cold water is applied to the head in acute cerebral congestion, and to the spine in chorea, etc.; also locally in hemorrhoids, bubo, orchitis, and to the uterus in postpartum hemorrhage. Cold effusion to the body is employed as a preventive of spasmodic croup, as well as to lessen the tendency to taking cold.

"*Hot water* externally as fomentations, hot wet pack, hot baths, etc., is most effective in reducing local congestion and in setting up resolution of local inflammation. Hot fomentations to the renal region are useful in functional inactivity of the kidneys. The hot spinal douche is used in affections of the spinal cord and meninges, and in the backache of women. The hot wet pack is highly esteemed in inflammation of the chest organs, and hot injections are useful in chronic inflammation of the uterus. Hot water dressings for wounds are strongly favored by many surgeons. Vapor and Turkish baths are used as diaphoretics in advanced kidney disease, in acute and chronic rheumatism, in mineral poisoning, and in syphilis. Warm baths, with cold applications to the head, are of value in infantile convulsions and chorea."—(*Cyclopedia of Medicine and Surgery.*)

8. Urotropin, when taken, is decomposed in the body and formaldehyde is liberated and eliminated in the urine; hence it is used as a urinary (and intestinal) antiseptic, dose gr. iv., administered in water.

9.

Official Preparations of Mercury	Chiefly Indicated in:
Ammoniated mercury	Ozæna, psoriasis, tinea, and other skin affections.
Bichloride of mercury	Syphilis, anemia, summer diarrhea
Calomel	Syphilis, biliousness, dropsy, dysentery.
Red oxide of mercury	Syphilitic sores, chronic skin diseases.
Yellow oxide of mercury	Indigestion, syphilitic sores, chronic skin diseases.
Red iodide of mercury	Syphilis, acute tonsilitis
Yellow iodide of mercury	Chronic Bright's disease, syphilis
Solution of mercuric nitrate	Epitheliomata, warts, lupus
Ointment of mercuric nitrate	Chronic skin diseases.

10. Cocaine hydrochloride. *Physiological action:* local anesthetic (externally); internally it is a muscular, cerebral, circulatory, and respiratory stimulant, also a mydriatic. Its *principal uses* are: As a local anesthetic; also in paralysis agitans, chorea, and alcoholic tremors.

(*To be concluded.*)

Vaccine Virus Free from Bacterial Contamination.—Noguchi has succeeded in freeing vaccine virus from all associated bacteria by means of suitable disinfecting agents, and in propagating it thenceforward in a pure state in the testicles of rabbits and of bulls. The virus thus cultivated appears capable of indefinite transfer from one animal to another without loss of its potency. The method of preparation is sufficiently satisfactory to be practicable from the commercial standpoint.—*Journal of Experimental Medicine.*

Pontine Polioencephalitis.—J. Collier reports the case of a boy aged 8 years who was taken suddenly ill on January 18 with headache and fever. During the following two days he had a series of convulsions, vomited repeatedly, and was in a stuporous condition. Subsequently he was noisy and restless for a few days and then seemed quickly to recover, except that he was completely deaf and was very unsteady upon his legs. He was completely deaf when he was examined on February 16. The ears were normal. He talked and obeyed written orders very intelligently. The vibration sense was present. There were nystagmus, bilateral ataxia, titubation, and a cerebellar gait. Lumbar puncture revealed a normal cerebrospinal fluid. The Wassermann reaction was negative. Under observation the cerebellar signs have practically disappeared, leaving complete deafness as the feature of the case.—*Proceedings of the Royal Society of Medicine.*

Miscellany.

A Premium on Live Babies.—In 1904-5 Mr. Benjamin Broadbent was mayor of Huddersfield, and offered to present each child born in Longwood, during his year of office with a sovereign on its attaining the age of twelve months. His offer resulted in his giving out 112 promissory notes, to be redeemed on the child attaining the age of twelve months. Of these 107 were presented for payment. A few days ago he held a garden party at his residence, to the "Mayor's Sovereign Babies," as they had come to be known. His guests numbered 88. A few children could not be present and some could not be traced owing to removals. Mr. Broadbent's offer ten years ago caused increased attention to be given to the health of the local babies, and in the one year the infantile death rate at Longwood was reduced from 122 per 1,000 births to below 50, while in the rest of Huddersfield the figure was 139, about the same as in the previous year, and it was claimed that the experiment demonstrated that a huge saving in infant life could be effected. The infant death rate is now 96.—*The Lancet.*

A Nation-Wide Medical Examination Day.—As one of the pioneers in the inauguration of routine physical examinations of employees, this department welcomes the announcement just made by the National Association for the Study and Prevention of Tuberculosis of a National Medical Examination Day as part of the plans for Tuberculosis Week, December 6 to 12, 1915. In a paper read nearly two years ago Commissioner Goldwater spoke of the inauguration of universal periodic medical examinations as "the next great step in preventive medicine," and pointed out that they constituted "an indispensable means for the control of all diseases, whether arising from injurious personal habits, from congestive or constitutional weakness, or from social and vocational conditions." Medical Examination Day is set for Wednesday, December 8, and will be the first effort on a national scale to urge an annual physical examination for everyone. Plans for the day include an appeal to induce everyone, sick and well, to see a doctor and learn whether he or she is in good physical condition. The scheme includes also the inauguration on the part of factories, stores, and offices of an annual physical examination for all employees. Thousands of antituberculosis associations, other societies, and dispensaries all over the country are expected to cooperate in furnishing free examinations for those not able to pay a physician. Children's Health Crusade Day on Friday, December 10, is planned to interest and instruct school children in healthful living. Special exercises will be held at which lectures, essays, and playlets will be given on the subject of health. This will also be the occasion for launching the Red Cross Christmas Seal sale in the schools. The culmination of the campaign will be the sixth annual celebration of Tuberculosis Sunday. Last year on Tuberculosis Day over 100,000 churches in the United States gave attention to the subject. The governors of all the States will be asked to issue proclamations calling attention to the importance of increasing the knowledge of the public on how to avoid consumption. Clubs, lodges, and societies will also be asked to consider the subject at a meeting either on Tuberculosis Sunday or on some other day of Tuberculosis Week.—Weekly Bulletin of the New York City Department of Health.

A STUDY OF 59,270 EXPOSURES OF ORDINARY LIFE INSURANCE SHOWING URINARY IMPAIRMENTS AT THE TIME OF ACCEPTANCE.*

BY J. BERGEN OGDEN, M.D.,

NEW YORK.

ASSISTANT MEDICAL DIRECTOR OF THE METROPOLITAN LIFE INSURANCE COMPANY OF NEW YORK.

SOME twenty-four years ago the writer, while engaged in research work was forcibly impressed with the fact that many individuals who applied for insurance on their lives were unable to obtain policies because of some abnormality in their urine. No small number of these people went to their physicians or to medical chemists and analysts to find out the real reason for being declined insurance. In this way I came into close touch with those who at the time or at some previous time, had been the subjects of abnormal urine. It was not uncommon to find in these cases evidences of extensive kidney disease, a diabetes mellitus or some disease of the urinary tract which had been unsuspected up to the time application was made. But it also not infrequently happened that some of these unfortunate individuals presented evidence of disturbance in the urinary tract which entirely disappeared within a short period. Subsequent experience with cases of this kind led me to believe that at least some of those who had been declined were entitled to insurance protection because they were not really diseased, but merely temporarily disturbed.

It was not many years ago that insurance was refused any person whose urine contained albumin or sugar, or when the specific gravity was uncommonly high or unusually low, or when the reaction was alkaline. To-day these abnormal, or unusual features of the urine are looked upon by many of us merely with suspicion and, by means of thorough chemical and microscopical investigation and study, a fairly correct translation of their significance can be made.

It is, therefore, with great pleasure that I am today able to present to this Association the results of a study of 59,270 insurance exposures covering a period of about ten years.

It may interest you to know something of the manner of collecting the data which will be presented.

The laboratory of the Metropolitan Life Insurance Company was created in July, 1905. It was deemed advisable at that time to make thorough and systematic chemical and microscopical analyses of the urine, for the purpose of selecting those individuals for insurance risks who presented relatively unimportant disturbances in the urinary tract, and at the same time eliminate those cases which showed well-marked pathological conditions in the urinary system. The *modus operandi* of investigating the urine adopted in 1905 has been in use ever since.

Specimens of urine are sent to the Home Office by first-class mail from all parts of the United States and Canada. The examiners in the field are requested to mail a specimen of urine in every instance where they find either albumin or sugar, where the specific gravity is above 1030 or below 1012, where the history of circumstances suggest the advisability, and when the policy applied for plus that already carried in this company amounts to $10,000 or more. In addition to specimens received under these circumstances, the Home Office frequently requests the examiner to send samples because of a personal history or a suspicion of some trouble in the urinary tract.

The methods of urinary analysis used by the examiner in the field are those adopted by this Association in 1908, and the same methods are in use in our Home Office laboratory, although our laboratory investigation of the urine is much more extensive than that made in the field by the Medical Examiner.

Chart I will serve to show the nature of our laboratory study of the urine, and every specimen coming to our Home Office receives exactly the same analysis.

CHART I

Sugar =

Sediment =

Recommendation:

Accepted — Postponed — Rejected

The color, reaction, and transparency are noted, the relative amounts of uric acid and chlorides determined, the percentage of urea obtained, and the tests for albumin, sugar, bile pigments, acetone, and diacetic acid are made. The sediment is examined in every instance, except in those urines which contain a large quantity of sugar, and in rare instances where the amount of albumin is very large and the case is obviously so bad that we do not deem it necessary to complete the examination.

Since the microscopic examination of the urine constitutes perhaps the most valuable part of a

*Read at the Twenty-sixth Annual Meeting of the Association of Life Insurance Medical Directors of America, Oct. 15, 1915.

urinary analysis, it may be of interest to know just how these examinations are conducted in our laboratory. The urinary sediment is obtained by centrifugalizing 15 c.c. of the urine which has first been thoroughly agitated. If upon examination a satisfactory sediment is not obtained in this way, the urine is allowed to settle for several hours by gravity and the deposit thus obtained is thoroughly centrifugalized. One or more microscopic preparations are then made and examined. No specified time is given to the microscopic examination. Some sediments are examined quickly while others require a much longer time, but since all microscopic examinations are made by trained assistants, much must be left to the judgment of the microscopist as to the time to be spent on any given sediment. Roughly speaking, an average of six or eight sediments per hour is about the number which can be satisfactorily examined by one person.

Of all of the cases in which the urine is sent to the laboratory of the Metropolitan Life Insurance Co., because either the Medical Examiner found at the time of his examination the abnormal features or there was a history or a suspicion of trouble in the urinary tract at some previous time, approximately 68 per cent. are recommended for insurance on the regular plans. If we include those cases in which the examiner sends the urine to the Home Office laboratory because of the amount of insurance—$10,000 or more—and in which his examination of the urine is negative, approximately 71 per cent. are favorably recommended for insurance on the regular plans. The cases under consideration to-day are those that were thus recommended by the writer and finally accepted as suitable risks.

For the purpose of analyzing the 59,270 exposures, we have divided them into ten groups according to the urinary impairments found, at the time of acceptance, by the chemical and microscopical examinations of the urine, and we shall now consider each impairment, giving the figures which have been very carefully prepared by the Actuarial Division of the Metropolitan Life Insurance Company. The impairments are numbered from 1 to 11, omitting number 10 in which no data are yet available. No substandard or special class cases are included in these figures and groups, but only those accepted on some of the regular plans of ordinary policies issued by the company.

The period of time covered by this study is practically ten years. Our records, however, antedate the opening of the laboratory because of a few revival cases which carry the dates of issue back to 1904, and then through the succeeding years to and including 1913. All exposures are taken to their anniversary date in 1914.

We shall take up the different impairments giving the exposures by number and by amount of insurance involved, the probable claims computed on the American Experience and on the Compound Progressive tables, the actual claims by number and amount of insurance, and finally the percentages of actual claims to the probable on both tables. It will be obvious that our final basis of calculation is therefore reduced to percentages.

GROUP. 1. *Slightest possible trace of albumin. Relatively normal solids.* (1.5 *per cent. to* 2.5 *per cent. urea.*) *Rarely a cast (hyaline or granular), renal cell and abnormal blood globule.*

This group of cases represents a very mild renal disturbance which we term a mild renal congestion or active hyperemia, and not true kidney disease. These are the cases which have been the terror of the insurance world and considered by some as extra hazardous; others have believed that they were suitable for policies only on a substandard plan.

Practically all of the cases accepted in this group were comparatively young people, under 40 years of age, with a first-class history in every other respect. The amount of insurance applied for and given was usually small, varying from $1,000 to $2,000 and in very few were blood pressures taken. We have looked upon the kidney disturbances in these cases as a transitory condition likely to last only a few days and then entirely disappear. It is reasonable to believe that temporary derangement is as likely to occur in the kidney as in any other organ of the body, and without affecting longevity. To be sure, the important feature of these cases is to distinguish them from those showing renal disease in its early stages, and this is not always an easy matter with the limited means of investigation at our command.

In this group there are 5,546 exposures involving $8,154,400 insurance. The probable claims amount to 58+ in number and $87,645 in amount calculated on the American Experience table, and 40.7+ in number and $62,135 in amount on the Compound Progressive table. The actual claims were 31 in number and $41,200 in amount, giving us 53 per cent. by number and 47 per cent. by amount on the American, and 76 per cent. by number and 66 per cent. by amount on the Compound Progressive tables.

By referring to Table XVIII, we find that, of the 31 claims, only ten causes of death have a direct or indirect connection with the kidneys. There were two deaths from Paralysis, five from Organic Heart Disease, one from Embolism or Thrombosis, and three from Nephritis or Bright's Disease.

GROUP 2. *Slightest possible trace of albumin. Relatively normal solids. Excess of leucocytes and urethral or neck-of-bladder cells. Some squamous epithelium. Rare or occasional blood globules. No casts found.*

The condition represented by these findings is one of a slight irritation in the urinary tract below the kidneys and ureters. The source of the slight irritation or congestion is shown by the cellular elements found in the microscopic examination of the urinary sediment. The disturbance may be in the bladder, at the neck of the bladder, in the prostatic urethra, the urethra proper, or in the prepuce. In the great majority of instances the irritation is in the urethra and at the neck of the bladder. Occasionally there is a slight disturbance in the bladder and not infrequently a long prepuce with lack of proper cleanliness is the source of the elements found in the sediment. Apparently the most frequent cause of this slight irritation in the urethra and prostatic region is a pre-existing gonorrhea which has left a small area which has never fully recovered. Sometimes fine urethral shreds are found which no doubt come from slightly inflamed folds of the mucous surface of the urethra. Cases of this sort must not be confused with those of urethral stricture in which there is usually a pocket of pus behind the constriction in the urethra.

In this group are also included female risks in which the urine almost always shows a greater or

smaller number of elements from the genital tract and genitalia. Naturally, in the female, there may also be slight disturbances in the bladder and urethra.

We look upon the conditions in this group, as relatively unimportant and in no way affecting longevity. This group is a large one for the condition is very common. The number of exposures is 23,061 involving $76,567,900 of insurance. The probable claims are 227.5+ in number and $823,210 in amount on the American Table and 146+ in number and $541,728 in amount on the Compound Progressive Table. The actual claims were 94 in number and $300,900 in amount, making 41 per cent. by number and 37 per cent. by amount on the American, and 64 per cent. by number and 56 per cent. by amount on the Compound Progressive Tables.

In Table XVIII, it will be seen that of the 94 death claims, only a comparatively few causes of death were directly or indirectly connected with the urinary tract. We find one death from Alcoholism, one from Chronic Lead Poisoning, one from other Chronic Poisoning, three from Cerebral Hemorrhage or Apoplexy, one from Paralysis, one from Pericarditis or Acute Endocarditis, four from Organic Heart Disease, one from Angina Pectoris, one from Embolism or Thrombosis, and four from Nephritis or Bright's Disease.

GROUP 3. *No albumin detected. Relatively normal solids. Rarely a hyaline or granular cast, renal cell, and blood globule.*

In this group the urine was found to be free from albumin, the solids were relatively normal, but in the sediment were found rarely a hyaline or granular cast, renal cell, and blood globule. In other words, there was evidence of a slight disturbance of the kidneys, but without any trace of albumin and without evidence of disturbance in other parts of the urinary tract. There is, in this group, a striking similarity to Group 1 except for the absence of albumin. Practically all of the risks were under 40 years of age, and invariably with a first-class history in every other respect. Because of the care in selection, and the relative infrequency of finding casts in the urine without albumin, the number of cases in this group is small and perhaps too small to give us a good idea of the true mortality, but the figures are submitted for what they are worth. I might add that these risks were taken with the conviction that there was not true renal disease present, but that our findings in the urine represented only a very slight temporary renal irritation or congestion which was not of importance as affecting longevity.

The number of exposures is 503, involving $1,025,400 of insurance. The number of probable claims is calculated as 5.3+ in number and $12,346 in amount on the American Table and 3.7+ in number and $9,155 in amount on the Compound Progressive Table. There was only one $1,000 claim giving 19 per cent. by number and 8 per cent. by amount on the American table and 27 per cent. by number and 11 per cent. by amount on the Compound Progressive Table.

The reported cause of death of the single claim in this group was Pneumonia. (Table XVIII.)

GROUP 4. *No albumin. Low specific gravity (1,012 or less). Relatively low urea (1.5 per cent. or less). No casts or other morphological elements detected.*

One of the most perplexing group of cases in judging of the fitness of applicants for insurance is that showing persistently low specific gravity (below 1,012) and a low percentage of urea (below 1.5 per cent.). In this group we have the low solids without albumin or sugar and without abnormal elements in the sediment. With a specific gravity below 1,012 and a correspondingly low percentage of urea 1.5 per cent. or less, there immediately arises the question of a cause. We know that the nervous excitement attendant on the physical examination of the applicant for insurance is nearly always present and this constitutes a common cause of a low specific gravity of the urine—a nervous hydruria. It is, therefore, always advisable to procure a specimen of urine from the applicant, if possible, before the physical examination is begun rather than to wait until the examination has been completed, as is the rule.

Another common cause of low solids is the ingestion of an unusual amount of water, beer, or other fluid. It is not uncommon for the laboring man to stop at a saloon on his way from the shop to have a glass of beer or to have beer with his meals, and usually the urine collected shortly after will have a low specific gravity.

Still another cause of low solids is a chronic interstitial nephritis, and right here lies the great importance of the condition from an insurance standpoint. We all know how very difficult it is to detect albumin and renal casts in a very dilute urine, and the possibility of dealing with an interstitial nephritis is, therefore, apparent.

It has been our effort to determine in every instance the cause of the low specific gravity if possible. We make repeated examinations of the urine, and ask the help of the Medical Examiner in the field to get at the cause and to obtain further samples of urine after the applicant has abstained from any excess of liquid for several hours.

In this group the risks were taken while the solids were low—persistently low. The number of exposures is 7,401 representing $11,941,100 of insurance. The probable claims calculated on the American Experience Table is 68+ in number and $114,973 in amount, and on the Compound Progressive Table 43.7+ in number and $75,522 in amount. The actual claims were 34 in number and $68,500 in amount, giving us 50 per cent. by number and 60 per cent. by amount on the American, and 78 per cent. by number and 91 per cent. by amount on the Compound Progressive tables.

In Table XVIII, we find that of the 34 actual claims in this group, only four reported causes of death have any direct or indirect relation to the urinary tract. There was one death from Cerebral Hemorrhage or Apoplexy, one from Organic Heart Disease, one from Cirrhosis of the Liver, and one from Nephritis or Bright's Disease.

GROUP 5. *Slightest possible trace of albumin. Low specific gravity. Relatively low urea. Excess of leucocytes and neck of bladder and urethral cells. Some squamous epithelium. Rarely a blood globule. No casts found.*

In this group we have a study of low solids accompanied by evidence of a mild disturbance in the lower part of the urinary tract. Except for the relatively low solids, the condition of the urine is very much like that in Group 2.

The usual causes of low solids have already been considered under Group 4, but here, with the presence of a small amount of albumin, the danger of a chronic interstitial nephritis is, if anything, greater

than in Group 4. It, therefore, remained for us to determine by all available means that a chronic nephritis did *not* exist. The study of a number of specimens obtained under varying conditions and particularly of samples obtained after the applicant has avoided any excess of liquids for a number of hours was essential. A reliable and observing Medical Examiner will generally find out the cause of a low specific gravity especially if due to the ingestion of an excess of liquid. Of infinite help also is the absence of a history or any physical signs pointing to a serious kidney disease.

The insurance risks in this group have, therefore, been the subjects of sufficient study to satisfy us of a reasonable cause for the low solids before issuing a policy, and our experience has thus far been a favorable one. The number of exposures is 4,348, involving $10,103,700 of insurance. The probable claims were calculated as 41.5+ in number and $113,700 in amount on the American, and 26.7+ in number and $77,876 in amount on the Compound Progressive tables. The actual claims were 21 in number and $36,700 in amount, making 51 per cent. by number and 32 per cent. by amount on the American Experience, and 78 per cent. by number and 47 per cent. by amount on the Compound Progressive tables.

Of the 21 actual claims in this group we find, by referring to Table XVIII, that seven causes of death have a direct or indirect connection with the urinary tract. There were three deaths from Organic Heart Disease, one from Cirrhosis of the Liver, one from Simple Peritonitis, one from Nephritis or Bright's Disease, and one from Diseases of Pregnancy.

GROUP 6. *Slightest possible trace of albumin. No sugar found. High specific gravity (1,030 or more). Relatively high urea (2.5 per cent. or more). Occasional blood globule, few leucocytes and cells from urethra or neck of bladder. Excess of mucin. No casts found.*

This group has been introduced into our studies to learn the real significance of a concentrated urine, whether temporary or permanent, as an element in longevity. This class of cases is in many respects like those of Group 2 except that the urine is highly concentrated. The specific gravity is 1,030 or more and the percentage of urea 2.5 or higher. The morphological elements in the sediment are about the same as in Group 2.

In this group we find more particularly the disturbing or irritating action of a concentrated urine on the mucous membrane of the lower part of the urinary tract, as indicated by the elements in the sediment. While this condition is not uncommon in the male, it is very often seen in the female, the probable explanation being that women take less liquid than men.

We also find in this class of cases the lasting effects of an old gonorrhea, without urethral stricture. We all know how commonly this condition exists, but without any effect on the length of life. We have, therefore, looked upon this group as relatively unimportant.

The number of exposures in this group is 10,870 representing $27,765,900 of insurance. The probable claims are 100+ in number and $268,741 in amount on the American, and 62.5+ in number and $169,981 in amount on the Compound Progressive tables. The actual number of claims is 42 in number and $120,700 in amount, giving us 42 per cent. by number and 45 per cent. by amount on the American Experience table, and 67 per cent. by number and 71 per cent. by amount on the Compound Progressive table.

In this group there were 42 actual claims and of these only six causes of death appear to be in any way connected with the urinary system (see Table XVIII). There was one death from Chronic Lead Poisoning, one from Cerebral Hemorrhage or Apoplexy, one from Embolism or Thrombosis, one from Simple Peritonitis, one from Nephritis or Bright's Disease, and one from other Diseases of the Kidneys and Annexa.

GROUP 7. FIRST EXAMINATION: *Slightest possible trace of albumin. Relatively normal solids. Rare or occasional hyaline and granular casts. Occasionally or rarely a blood globule.* SUBSEQUENT EXAMINATIONS: *Slightest possible trace, or no albumin. Relatively normal solids. Rarely a blood globule, excess of leucocytes, and neck of bladder or urethral cells, or sediment negative.*

In this group of cases we found at our first examination in the Home Office Laboratory evidence of a slight renal disturbance similar to what we found in Group 1. These cases were not considered insurable at that time. One or more samples of urine were requested after two, three, or four weeks, and our further study satisfied us that the condition originally found had disappeared and then policies were issued on the regular plans. The greater number of cases in this group were between the ages of 13 and 57 as will be seen by referring to tables XIII, XIV, and XV, but in reality the majority were between the ages of 25 and 45 and very few, indeed, were accepted after the age of 50.

These cases were not considered eligible for Group 1 for a variety of reasons, but principally because of either the age, the occupation, or the history of albuminuria, kidney disturbance or disease at some earlier date. In studying the applications and all of the facts presented, the Medical Director had a desire to know more about the urine before making a decision, and in every instance the further study of the urine demonstrated pretty clearly that the urinary findings at the original examination represented only a temporary renal disturbance of the nature of a mild irritation or congestion of the kidneys and of no serious importance.

The number of exposures in this group is 4,152, representing $11,798,500 of insurance. The probable claims are 42.8+ in number and $131,797 in amount on the American Table, and 28.7+ in number and $89,643 in amount on the Compound Progressive Table. The actual claims were 20 in number and $41,500 in amount, making 47 per cent. by number and 31 per cent. by amount on the American, and 70 per cent. by number and 46 per cent. by amount on the Compound Progressive tables.

By referring again to Table XVIII we find that of the 20 actual claims, only a comparatively few deaths have any direct or remote connection with the urinary tract. There was one death from Diabetes, one from Pericarditis or Acute Endocarditis, two from Organic Heart Disease, and one from Nephritis or Bright's Disease.

GROUP 8. FIRST EXAMINATION: *Very slight trace of albumin. Relatively normal or high solids. Few hyaline and granular casts, with renal cells and blood adherent.* SUBSEQUENT EXAMINATIONS (*After three months*): *Slightest possible trace or absent albumin, relatively normal solids. No casts found. Rarely or absent blood globules and leucocytes.*

Here we have a marked renal disturbance as is shown by the decided trace of albumin and a good number of casts, some of which have blood and renal cells adherent. This condition of the kidneys might well be a rather severe irritation, or, perhaps, a chronic disease of the kidneys with a mild active or acute condition superimposed. With the solids of the urine relatively normal and a negative clinical history in a person under 40 years of age, it is fairly safe to decide that the kidney condition probably belongs to the class of renal congestion or irritation secondary to some disturbance outside the urinary tract. It has been our custom to treat these cases as probably temporary derangements of the kidneys and postpone action for a number of months and then reconsider them. If, after the lapse of two or three months, examinations of a number of specimens of urine showed an absence of casts and either a perfectly normal urine, or only a slight local disturbance below the kidneys, the risks were accepted. In other words, the marked disturbance of the kidneys had to the best of our knowledge been only temporary and had entirely cleared up at the time the risks were assumed.

The number of exposures in this impairment is 818 with $1,160,900 of insurance involved. The probable claims were calculated to be 7.1+ in number and $11,820 in amount on the American table, and 4.4+ in number and $7,694 in amount on the Compound Progressive table. The actual number amounted to one $1,000 claim, giving 14 per cent. by number and 8 per cent. by amount on the American Experience table, and 23 per cent. by number and 13 per cent. by amount on the Compound Progressive table.

Notwithstanding this favorable showing in a ten-year period, I must confess a feeling of some anxiety as to the results we shall obtain in from 15 to 20 years for the reason that, in this particular group of cases, the character of the urine varies greatly from week to week. There is, therefore, a likelihood of accepting risks who have an important kidney disease. This danger is increased because of our limited means of getting at the true condition through the urine or by physical examination.

After a long study of the cases such as we encounter in this group, I am unable to explain satisfactorily why the urine to-day will show a decidedly unfavorable appearance and a week or so later will be practically normal, but still another week later will be as unfavorable as the original specimen of urine. But such is the fact, and it is needless for me to say that where the improved condition of the urine was not found constant, the cases were not accepted for insurance. Although our figures for this impairment are comparatively small, yet they are satisfactory for about ten years, but it is at the same time clear that these risks must be selected with great care.

The reported cause of death in the single claim in this group was Disease of the Intestines.

GROUP 9. FIRST EXAMINATION: *No albumin. Relatively low solids. No casts or blood or other morphological elements.* SUBSEQUENT EXAMINATIONS: *No albumin. Relatively normal solids. No casts or blood or other morphological elements found.*

We have here a group of insurance risks in which the urine, at the first examination, showed nothing of importance except relatively low solids—a specific gravity below 1,012, and less than 1.5 per cent. of urea. At subsequent examinations of the urine after one, two, or even four weeks, the solids were found to return to the normal and the urine was in other respects found to be perfectly normal. Most of these cases were less than 45 years of age at the time they applied for insurance, and the greater number of them were between the ages of 25 and 40 years.

These risks were not considered eligible for Group 4, at the first examination, and subsequent analyses of the urine were deemed advisable to ascertain whether the solids were persistently or only temporarily low. Usually we were able to learn through the Medical Examiner in the field the most probable cause of the low specific gravity of the first specimen of urine, and the policy was then issued.

The number of exposures in this group is not very large, there being only 1,177, involving $3,813,400 of insurance. The probable claims were calculated to be 12.4+ in number and $38,200 in amount on the American Experience, and 8.7+ in number and $26,214 in amount on the Compound Progressive tables. The actual claims amounted to 9 in number and $13,000 in amount, giving us 72 per cent. of the expected by number and 34 per cent. by amount on the American, and 103 per cent. by number and 50 per cent. by amount on the Compound Progressive tables.

The percentages in this group are exceptionally high and probably due to the comparatively small number at risk. We should expect a low percentage in this group because of the fact that the urine was perfectly normal at the time the risks were taken, and I believe that as the number of cases at risk increases we shall see a substantial drop in these figures.

In this group there were nine actual claims and of these only three deaths appear to be in any way connected with the urinary tract *i. e.* three deaths from Organic Heart Disease. (Table XVIII.)

GROUP 11. FIRST EXAMINATION: *Slightest possible trace, or absent albumin. Relatively normal solids. Sugar present varying from very slight trace to a large trace. Occasionally or rarely a blood globule and excess of leucocytes, and neck of bladder or urethral cells. Rarely a hyaline and granular cast, or, no casts found.* SUBSEQUENT EXAMINATIONS: *Slightest possible trace, or absent albumin. Relatively normal solids. No sugar found by copper or phenylhydrazine tests. Occasional or rare blood globule. Excess of leucocytes and neck of bladder and urethral cells. No casts found.*

This is a study of glycosurias where the amount of sugar in the urine at the time of the original examination varied from a very slight trace to a large trace. At this first urinary examination there may have been also evidence of renal disturbance as shown by the presence of renal casts and renal cells, or there may have been evidence of a disturbance in the lower part of the urinary tract; in other words, there was usually some indication of a disturbance of some part of the urinary tract due to the irritating action of the sugar. Such cases were never granted insurance while the urine showed the presence of sugar, but they were postponed for a number of weeks or months with the belief that we were dealing with a temporary glycosuria. When, after a number of analyses of the urine obtained under varying conditions and at different times of day, the sugar was found to have disappeared and during the period of ob-

servation had not reappeared, policies of insurance were given on the regular plans. Very few, if any, of these cases were given insurance if they were heavy weights or if they were in any other way impaired, and particular attention was given to the age, very few being accepted below the age of 25.

As a class these cases have shown an unusually high mortality up to the eighth or ninth year of exposure, and just why this should be so I am unable to explain. As will be seen by Table XVIII very few have died of Diabetes Mellitus, but a possible explanation is that there was a lowered resistance to the action of acute diseases caused by the failure to convert sugars and starches into glycogen.

This number of exposures is not large, there being 1,394 involving $3,364,100 of insurance. The probable claims were figured to be 13.5+ in number and $34,866 in amount on the American Experience Table, and 8.79+ in number and $22,923 in amount on the Compound Progressive Table. The actual claims were 8 in number and $94,000 in amount, making 59 per cent. of the expected by number and 270 per cent. by amount on the American, and 91 per cent. by number and 410 per cent. by amount on the Compound Progressive tables.

Our figures by amount are very high, but by referring to Tables III and V it will be seen that we had one $25,000 claim in the first year of exposure and one $50,000 claim in the third year of exposure. These account for a large part of the $94,000 of claims and for our high percentages by amount on both the American and the Compound tables.

Of the eight actual claims in this group there were only two causes of death which appeared to be in any way connected with the urinary system (see Table XVIII). There was one death from Paralysis, and one from Organic Heart Disease. There were no deaths reported as the result of Diabetes.

To summarize our figures in these eleven groups, excepting Group 10 (see Table I), we have a total of 59,270 exposures, representing $155,695,300 of insurance. The probable claims in all groups were calculated as 576+ in number and $1,637,298 in amount on the American Experience Table, and 374+ in number and $1,082,871 in amount on the Compound Progressive Table. The actual claims were 261 in number and $718,500 in amount, giving us 45 per cent. of the expected by number and 44 per cent. by amount on the American Table, and 70 per cent. by number and 66 per cent. by amount on the Compound Progressive Table.

For a better understanding of the figures which have been presented, you are referred to Table III. Here we find a total of 19,564 cases at risk involving $57,563,800 of insurance. By adding these figures to the risks of the second year, the third year, the fourth year, etc., we have the total figures given in Table I. For example: A policy for $1,000 issued at age 30, if it remains in force three years, gives one year of experience during the first year at age 30, one year during the second year at age 31, and one year during the third year at age 32. We, therefore, have a total exposure of three years and $3,000.

In making up the probable claims our Actuary has used the same method of calculation as was employed in the Medico-Actuarial Investigation, the results of which have recently been published.

For comparison we have the figures in all of the Ordinary business, irrespective of whether analyses of urine were made or not made, for the years of 1905 to 1913 inclusive. The probable claims were calculated as 17,167 and the actual claims amounted to 8,627, giving 50.26 per cent. of the expected on the American table.

Table II.—Total Ordinary Business.

Issues of 1905-1913.

Experience of 1905 to 1914

Probable Claims	Actual Claims
17,165	8,627

Percentage of probable = 50.26.

It will be seen, therefore, that the figures for the risks having urinary impairments (Table I) are more than 5 per cent. under the average for all ordinary risks for the corresponding period of time.

These figures are rather astounding. Just why they are more than 5 per cent. under the average, I do not know. These cases were not treated in our Home Office any differently from those which showed no urinary impairments. We should expect a percentage a trifle above the average, and it is probable that, in 15 or 20 years of experience, a percentage somewhat above the average will obtain.

We have also given for your consideration an analysis of the issues of 1904 to 1913 inclusive in their different years of exposure.

Certain groups make an unfavorable showing when considered by years of exposure. For example, Group 11 (glycosurias) shows the effect of unusually large claims *by amount*. In the first year there was one claim of $25,000, in the second year four claims amounting to $17,000, and in the third year two claims amounting to $51,000, thus raising the average *by amount* of insurance for the ten years to 270 per cent., but calculated *by the number* of claims the percentage was 59 on the American Table. Some of the other groups were unfortunate in having exceptionally large claims *by amount* in some one or more years of exposure, and yet our averages for the ten years are very gratifying, as will be seen by referring to Table I.

Let us now consider the exposures by ages at entry. The Actuary has given us four classes, 13-27, 28-42, 43-57, and 58-72.

At the ages from 13 to 27 we find two groups rather high. No. 9 is large *by number*, 72 per cent., but probably due to the small number at risk. No. 11 is high *by amount*, due to the few large claims. At ages from 28 to 42 we find group 11 still high *by amount*, due to two claims, one for $50,000. At the ages from 43 to 57 we find groups 9 and 11 still high by both *number* and *amount*, apparently due partly to the small number at risk and partly to rather large claims by amount, particularly in group 11. At ages from 58 to 72, the number at risk is so small as to give us very little reliable data.

In Table XVIII we have the reported causes of

		31	94	1	34	21	42	20	1	9	8	261	$718,500

In Table XIX we have a condensed classification of the causes of death. There are 13 general classes and in column 1 are the claims showing urinary impairments; in column 2, the claims of 1912 on the issues of 1905 to 1912; in column 3, the claims of 1914 on the issues of 1892 to 1914; and in columns 4, 5, and 6 we have the percentages. Of the 261 claims we have 91 or 34.87 per cent. from General Diseases; 23 or 8.81 per cent. from Diseases of the Nervous System; 25 or 9.58 per cent. from Diseases of the Circulatory System; 24 or 9.2 per cent. from Diseases of the Respiratory System; 23 or 8.81 per cent. from Diseases of the Digestive System; 12 or 4.6 per cent. from Diseases (non-venereal) of the Genitourinary System and Annexa; 48 or 18.38 per cent. from External causes; and 12 or 4.6 per cent. from Ill-defined Diseases.

It will be seen that our highest mortality was from General Diseases and External causes, but that the percentages of claims with urinary impairments are very close to the percentages of claims of 1912, in the total issues of 1905 to 1912. It is interesting to note that in Diseases of the Urinary System and Annexa, we have 4.6 per cent. with urinary impairments while there was 7.37 per cent. in the total business issued during practically the same period. In Diseases of the Circulatory System there was 9.58 per cent. with urinary impairments as against 8.96 per cent. of the claims of 1912. The percentage with urinary impairments is here relatively high, probably partly due to the paucity of data, and partly to the fact that disturbances of the urinary system are very common in Diseases of the Circulatory System.

For the purpose of comparison we have included the claims paid in 1914 on policies issued from 1892 to 1914. Some of these policies were in force 22 or 23 years. While the length of time influences the cause of death in these cases, it is of interest to note that about the same ratios obtain as for the shorter period. The percentage of deaths from Diseases of the Genitourinary System and Annexa is not one-half the total percentage.

We have referred to the fact that the applicants for insurance showing the different urinary impairments, already considered, were accepted on regular plans issued by the Metropolitan. For the purpose of showing the distribution of the different kinds of policies among the 19,564 risks, you are referred to Table XX.

TABLE XX

Kind of Policy	Entire Issue	Per Cent. of Total	Urinary Impairments	Per Cent. of Total
Life Endt. at 85 Endt. at 90 Reduced Prem. Life	136,831	22.13	5,438	27 79
Ltd. Pay. Life Op. Life & Endt.	280,767	45 41	7,554	38 61
Regular Endts.	182,250	29 48	6,003	30 68
Miscellaneous	18,432	2 98	569	2 92
Total	618,280	100 00	19,564	100 00

It will be observed that for nine years in the Life, Endowment at age 85, Endowment at age 90, and Reduced Premium Life policies, the total issue amounted to 136,831 or 22.13 per cent. Those with Urinary Impairments amounted to 5,438 or 27.79 per cent.—just 5.66 per cent. above the average.

In the Limited Payment Life, and Optional Life and Endowment policies there was a total issue of 280,767 or 45.41 per cent., while those with Urinary Impairments amounted to 7,554 or 38.61 per cent. —or 6.8 per cent. below the average.

In the regular Endowment policies there was a total issue of 182,250 or 29.48 per cent. Those with Urinary Impairments amounted to 6,003 or 30.68 per cent.—just 1.2 per cent. above the average.

This table shows very clearly that the relatively low mortality in policies with some urinary impairment is not due to a large proportion of those in the Endowment class.

We propose to continue the study of these groups of impairments and, with a larger number of cases at risk, to make smaller subdivisions, from which valuable information should be obtained.

In conclusion, I wish to thank Dr. T. H. Willard, and Dr. A. S. Knight, Medical Directors, and Mr. James D. Craig, Assistant Actuary of the Metropolitan Life Insurance Company for valuable suggestions and help in the preparation of this paper.

THE FORM OF TYPHUS FEVER THAT IS ENDEMIC IN NEW YORK CITY.*

By NATHAN E. BRILL, M.D.,

NEW YORK.

I HOPE this audience will not be disappointed by my not presenting a formal paper. I am not to blame for this as the President of the Academy requested that the speaker give no formal paper, but present the subject of the evening in a simple talk, as he believed the subject could thereby be more forcibly brought to the attention of the members of the Academy than by the reading from manuscript. If, therefore, the presentation is deficient in detail and completeness, I will ask for indulgence.

It has been facetious but rather pertinently remarked by one of the great humorists that "the degree of civilization of a people is in direct proportion to the amount of soap used by them." If the speaker might paraphrase this epigram it would be found that it was very applicable to the subject of typhus fever. He would like to say, therefore, that the amount of typhus fever among nations was in *indirect* proportion to the amount of soap used. In other words, where cleanliness was not maintained, where the ordinary laws of hygiene were transgressed and neglected, there would be found typhus fever, with all its accompanying horrors. This form of fever was always in the train of conditions which were associated with personal filth, with segregation of people in confined quarters, with economic states which produced squalor and famine; finally it stood as an index of man's greed, of his lust of conquest, of his sociologic inefficiency. It therefore attended in the wake of wars, in the purlieus or districts of cities to which no laws of sanitation had been enforced, in prisons, ships, and other institutions where men had been herded together without the means being supplied for personal cleanliness, and in the hovels of poverty where soap was a luxury. In short, the disease under discussion appeared whenever conditions were favorable to the development of vermin, particularly of the body louse, with which the disease is now specifically associated as an etiologic factor, as was proven by the work of Nicolle, Comte, and Conseil in their experiments at the Pasteur Laboratory at Tunis, Africa.

The body louse, *Pediculus vestimenti*, explains the most of the epidemiologic factors of the disease, particularly its appearance and its spread.

Epidemic typhus fever has appeared in the past in all countries, and particularly in those where the social conditions were associated with poverty; thus in Ireland and Russia it was particularly prevalent both in disseminated epidemics and in persistent endemic form. In Russia it is prevalent to this day. Even America has not been spared in the past, as was evidenced by its occurrence in 1836, in 1847, in 1865, in 1881 and in 1893. In the latter two periods I had personal experience with the epidemics in New York City; in fact, my knowledge of typhus fever in its epidemic form has been derived from this personal contact as well as from literature.

To form a proper conception of this disease it will be necessary to divest from your minds all preconceived notions of the disease gained from textbooks and monographs. In none of these will you obtain anything like the characters of the disease as it now appears in its modified form in New York and other cities of the United States. It will also be necessary for you to learn that typhus fever exists in two forms, which in their clinical manifestations bear only a superficial resemblance; that the mild, attenuated, or endemic form is masquerading in strange garments with features so disguised as to have escaped entirely observation and to have been mistaken by almost everybody for a form of typhoid fever.

The object of the speaker is to show wherein the epidemic communicable form differs from the mild or endemic and less communicable form of this fever; for this purpose it may assist you to listen to a brief description of the picture of the more virulent type of the disease, or what we shall call epidemic typhus fever.

Epidemic typhus fever usually begins rather suddenly, with a chill or chilly sensation, though it occasionally may be preceded by two or three days of malaise and general body pains. Headache rapidly supervenes, and fever immediately appears. The headache increases in intensity and the fever is quickly augmented, so that on the second or third day the temperature of the patient may have reached its fastigium of 104° or 105° F. From this time on the fever remains constant, with only slight diurnal changes, in the form of a morning remission of rarely more than 1° F. On the fifth or sixth day from the onset an eruption makes its appearance near the axillary folds, on the back, and on the abdomen, in the order mentioned. The eruption is at first distinctly papular, each spot being about one-half of a millimeter high, ovoid in shape, dirty pink in color, not circumscribed by a well-defined border, but each spot seems to merge almost insensibly into the surrounding skin. When subjected to pressure the papule fades but does not absolutely disappear, as is readily seen when a glass microscope slide is used to produce the pressure when all the changes which the spot undergoes under pressure may be readily observed. The eruption rapidly involves more of the trunk and extremities, sometimes even the palms of the hand and the soles of the feet, though it rarely appears on the face excepting on the sides of the neck below the ears. When it reaches its full efflorescence the

*Remarks made in opening a discussion on typhus fever at the New York Academy of Medicine, October 21, 1915.

character of the eruption changes, usually on the eighth day of the disease; the spots become more of a rusty pink, are more easily discerned when under the pressure of the glass slide—that is, they fade much less, and now some of them show points of hemorrhage in their centers. These hemorrhagic spots become quickly a uniform purple, and no amount of pressure will cause any change in their appearance.

When the eruption has reached its height the headache begins to wane, and the sensorium of the patient shows a more profound involvement. Delirium, which may have been present, becomes a more prominent feature; it may appear in one of two distinct types: one as an active, wild, expansive form, in which the patient may fight with the attendant, or may suddenly jump out of bed and even attempt to throw himself from the open window; on the other hand, it may show itself as a low, muttering raving without the expression of ideas, rambling and incoherent. At this stage of the fever there is marked prostration and involvement of the entire muscular system, the afflicted one being in a condition of constant tremor, relaxed to such an extent that he may lie in a heap in the most dependent part of the bed. He is now entirely oblivious to what is going on about him; while he may obey an order to show his tongue, he may leave it protruded even when told to replace it. Somnolence, which was present in the beginning of the illness gives place to wakefulness, and the patient may lie completely prostrated, unconscious, with wide-open eyes, staring into vacancy, muttering, with trembling lips and trembling arms, or picking at the bed clothes, with all the signs of impending dissolution as evidenced by a very rapid, thready pulse and general cyanosis. On the thirteenth or fourteenth day, however, all these discouraging signs of a profound toxemia may quickly change with a sudden and critical fall in the fever; the temperature in the course of a few hours may decline to subnormal and the patient fall into a restful sleep, whereupon convalescence becomes established. When death results from the disease, which it does in from 11 to 60 per cent. of all hospital cases, varying according to the virulence of the epidemic, the age of the patient the stage of the epidemic, and similar factors, it occurs between the ninth and twelfth day of the disease, in most cases. A few patients die after the crisis, from the intense exhaustion, though this is the exception. There is no disease in which the transition from intense sickness to health is so sudden as in typhus fever. What I want to impress on you is the high mortality which this disease induces. Murchison, in statistics gathered from over twenty years of experience in the London Fever Hospital, gives the average percentage of deaths from typhus fever as 18.92 per cent. in 18,268 cases. This result corresponds fairly closely with Curschmann's observation regarding the mortality in the Berlin hospitals of 23.4 per cent., an "alarming mortality," as he designates it.

Epidemic typhus fever is a disease of the *winter months*, or rather is most prevalent in cold weather. When the warm summer months arrive the epidemic either wanes or dies out. This is borne out by the present epidemic in the Balkan States. Last winter we read of deaths by the thousands in that unfortunate country, but in the spring, or rather, early summer, on the arrival of the American Red Cross contingent, the epidemic was well on the decline, and after the summer very little was left.

The communicability of this disease is very marked; it matters very little whether it be by the body louse or by some other agent, though there is very strong reason to believe that it is only communicated by that parasite, the fact remains that the disease is very communicable.

To recapitulate briefly the main features of epidemic typhus fever: it is a disease accompanied by profound toxemia, marked by the signs of an intense blood infection, by a marked involvement of the nervous system, manifested by delirium, by excitement, by tremor, by somnolence, stupor, coma-vigil, and an unusually severe involvement of the muscular system as well, as shown by the tremor and physical exhaustion which are so often manifest.

Wherein does the second form of typhus, which we have called the endemic, or mild, or attenuated form, differ from the epidemic typhus fever? They both are alike in their onset, in the first stage of the eruption, in the critical decline, and both are not followed by relapse. In all other respects they differ.

The eruption in the mild form rarely goes to the hemorrhagic or purple stage. It is always an erythema probably induced by bacterial thrombosis in the capillaries, which influences the endothelium of the walls to permit the escape of serum and a few red blood cells into the surrounding skin tissues; thus while pressure will force back the blood above the thrombosed area, causing the spots to fade, the exuded contents will have stained the tissues over the spots so that the site of the eruption will always be apparent under pressure. In epidemic typhus fever the virulence of the organism (*Bacillus typhi-exanthematici*) disturbs the function of the endothelium of the capillaries to such an extent that the entire contents of the capillaries are extravasated into the surrounding skin, thus giving rise to hemorrhagic spots, which no amount of pressure will cause to fade, and certainly not to disappear. The eruption of the mild form is the same as that of the epidemic form only as far as the first stage of the latter is concerned. In about 2 per cent. of the cases of the former cases a hemorrhagic eruption has been observed by me.

One will look in vain in the mild form of this disease for the signs of a profound involvement of the nervous system, which is so common in the epidemic form. While in a few cases of the mild form which show a hyperpyrexia, there may be a slight delirium, it is always of a mild type, appearing only at night. The patient may appear apathetic, he sleeps a great deal, he can always be aroused, he is never, or rarely stuporous, he is never seized by maniacal excitement during his delirium; he can always tell his surroundings, he never goes into coma-vigil, nor will one observe muscular tremors, or subsultus, or carphology, which are so often seen in the epidemic form; involuntary discharge of urine and feces in the mild form has never been seen by me.

The headache which appears in both forms with the development of the infection, and which is severe in both, shows a decided difference in the mild form in that it becomes progressively more intense even up to the end of the illness, whereas in the epidemic form at the end of the first week it is rarely a source of complaint, but is displaced by the development of the more pronounced nervous manifestations, which then dominate the clinical picture.

The mortality in the mild form is less than one-quarter of 1 per cent. I have seen only one death in over four hundred cases which up to this time have been entered in our records at Mount Sinai Hospital. What a marked contrast to the mortality of 20 per cent. in the hospital cases of epidemic typhus fever seen by Murchison and Curschmann!

The period of greatest prevalence of the mild form is in the *summer months*, as directly opposed to the time of prevalence of the epidemic form, which is in the winter months. In the former twice as many cases occur in the second half of the year as in the first half, and a little less than 70 per cent. of all the cases appear in the months of July, August, September, and October.

A very decided difference occurs in the communicability of the two forms. While, as we have intimated, the epidemic form is one of the most communicable of all diseases, the endemic form shows no evidence of being at all communicable. In fact, up to this last spring I have never seen among my own cases any example of family or house infection. This question has been very carefully studied by me. Through the enthusiasm and helpful cooperation of the various members of my house staff, who visited the homes of patients who had been brought to the hospital with this disease, and who made searching inquiries and personal investigations with the object of finding some other member or members of the patient's family or some other inhabitant of the apartment or of the house suffering with the disease, we have been unable to find a single instance. In April of this year the first instance of man and wife being affected at nearly the same time occurred. This shows that the communicable factor in this form of the disease is a practically negligible one. It also demonstrates that the body louse is not an important factor in the production of this form of the disease. If it were, there ought to be more cases of contact infection; the disease ought to appear, not only in more than one member of a family or household, but even in the same tenement house. It has so far not been found under these postulates. If the body-louse were an important factor in the transmission of the endemic type of typhus fever, such cases of this type ought not to appear in the greatest number in the summer months, because that parasite dies in warm weather, as was shown experimentally by Anderson and Goldberger, who found that they could not keep it alive in retainers exposed to the warmth even of their pockets; they showed that a temperature of more than 20° C. was sufficient to cause its death and that the optimum temperature under which it flourished was between 12°-16° C. This would explain the incidence of the epidemic type of typhus fever in the cold months of the year and its absence in all warm and tropical countries. Cases of this type have only been reported from the high mountainous regions of such countries, where the heat is tempered by the altitude. Therefore, some other agent than the body louse must be looked for to explain the origin and the spread of the mild form of the disease.

It was on account of these decided differences in the clinical and epidemiological aspects that I believed when I had the honor of presenting the mild form of the disease to the recognition of the medical profession of New York, it could have no connection with typhus fever. All of you who read my communications on this subject will know that in the early articles I showed the possibility of this form of the disease, of which no mention had up to that time been made in any text book or monograph on typhus fever which I have ever seen, being a typhus fever; that I discarded that idea on account of the differences in the clinical and epidemiological features which existed between it and typhus fever in the form in which the latter was known to all clinical teachers in the civilized world. Let me read what I said in my early communication on this phase of the subject.

"In the case of an epidemic of typhus fever, in my opinion, it would be simply impossible to say that these cases which I have described were not mild typhus fever. The onset, the eruption, though subcuticular mottling is absent, the critical decline, the absences of relapses are almost identical in both. If one can believe that typhus fever has been so modified by modern conditions of hygiene as no longer to be communicable, that it exists at all times in a community, that it has lost its notoriously epidemic character, that it has been deprived of its grave nervous symptoms and of so much of its toxemia as to make it a non-fatal disease, then one can say that these cases deal with a modern typhus fever, or rather, with a peculiar typhus fever which has been evolved by modern improved hygiene and sanitation. . . . Clinically this disease resembles typhus fever more than it does any other disease, and I should have felt that I had offered nothing to our nosology if it had been proved that typhus fever had lost its virulence, that it was constantly present in a community, that it was not communicable, that when it was present epidemics of it did not occur, and that it was no longer a grave and fatal disease."

The unexpected has happened, and we now know for the first time that these very changes in the characters of typhus fever have really occurred, and that the form of this disease as it exists and has existed during the past twenty years in New York City and many of the cities of the United States does possess the very attributes which were not formerly conceived of by any of those who had been best qualified to teach us the true nature of this disease.

Even the demonstration of the cross immunity experiments of Anderson and Goldberger did not convince me of the identity of these two forms for the reasons which I have elsewhere stated, and which I need not now recall. It was the epoch-making work of my student and pupil, Dr. Harry Plotz, who isolated the organism of the mild form and that of the epidemic form of this disease, which he found to be identical in all respects, which proved that the disease which I described is typhus fever, and is nothing else. Therefore I stand now prepared to chant a requiem or speak a funeral oration over so-called "Brill's Disease," even though I had no part in giving such a name to it. In fact, I always spoke of that disease as being "an acute infectious disease of unknown origin," mainly because I have a dislike to the eponymic designation of diseases and also because I did not believe that its existence as a separate disease had been sufficiently established. The work of Dr. Plotz has been to my mind convincingly corroborated by the equally brilliant work of his collaborator, Dr. Peter K. Olitzky, in the serological aspects, a description of which you will now have the pleasure of hearing. I am thoroughly convinced that the work of these men has established the etio-

logical factor of typhus fever in its two forms, and that that dread disease is no longer a disease of unknown origin, but that it is due to the invasion of the body by the *Bacillus typhi-exathematici.*

48 West Seventy-sixth Street.

THE VALUE OF IMMUNIZED MILK AS A PROPHYLACTIC AND REMEDY FOR TUBERCULOSIS.

By JULIUS ROSENBERG, M.D.,

NEW YORK.

In response to many inquiries and requests for information regarding the present status of immunized milk, the writer reports upon the most recent investigation of the principles and functions of immunized milk and the results from its use as a remedy and preventive of pulmonary tuberculosis.

He also considers this an opportunity to ask for the cooperation of the medical profession, to further and advocate the use of immunized milk, as an infant milk for incipient cases and the early stage of pulmonary tuberculosis, disease of the glands and bones, and other types of tuberculosis —to impress upon all, in a position to help, directly or indirectly, the urgent need of facilities and means to produce and supply immunized milk; to demonstrate its efficacy as a remedy and a prophylactic. Immunized milk provides, at the price of a high grade milk, both a food and a remedy.

As a commentary and explanation of the function of immunized milk, a brief review and reference to some of the writer's recent publications are advisable, especially to "The Investigation of the Tuberculosis Problem";[1] "The Rapid Increase of Cattle Tuberculosis and Its Serious Effect Upon Health and Life of Infants and Young Children";[2] "The Antituberculosis Crusade."[3]

For the purpose of obtaining the true facts to find the correct death rate of pulmonary tuberculosis, the writer collected and tabulated the official reports and statistics of every State and large city of the United States (publishing vital statistics) and the principal European capitals. The report and the writer's tabulation disclose present-day conditions throughout the world and especially in the United States, and prove that the death rate of pulmonary tuberculosis continues unchanged, with perhaps a fractional decline in a few cities, which may be consequent upon a shifting of patients from city to State institutions; and that sickness and mortality of other types of tuberculosis, especially of the glands, bones, and joints, and among children has increased. Here are a few examples of many:

In six cities in the United States in 1908 with a population of 1,615,000 there were 2,960 deaths from pulmonary tuberculosis; in 1913 in a population of 1,848,000 there were 3,144 deaths from pulmonary tuberculosis. In thirteen cities representing every section of the country, in 1910, with a population of 5,184,000, there were 8,751 deaths from pulmonary tuberculosis; in 1912, with a population of 5,443,000, there were 8,641 deaths from pulmonary tuberculosis. In six States, including the State of New York, with almost 16,000,000 inhabitants, there were in 1909 21,968 deaths and in 1912 22,472 deaths from pulmonary tuberculosis.

Other tabulations give practically the same results. These results are surely disappointing—their most liberal interpretation cannot warrant the optimistic misleading statements which flood the medical and lay literature.

Where is the evidence to justify the prophecy "The End of Tuberculosis Is in Sight"? What basis for the conclusion published by the London Government Board that "Consumption will disappear, the disease continually decreases in the great centers of population"?

The writer collected the latest reports from the cities of London, Manchester, Liverpool, and Edinburgh, especially mentioned in the reports, and found no evidence of conditions changed for the better. Such statements are misleading, create confidence and a feeling of assurance in what is done to combat tuberculosis, which are not justified by achievements of the past or prospects of the future.

The writer does not criticize what has and is being done, but the results of many years' effort are surely disappointing. He believes in the ultimate control of the great white plague, but not by the means and methods now employed. The present-day death rate of pulmonary tuberculosis stands as unimpeachable evidence of their inadequacy. The world-wide antituberculosis crusade, carried on for years with zeal and enthusiasm, has been of inestimable value as an educator to the public in sanitation. The recognition, by men of all classes, that spitting means danger to others and from others, has made it possible to enforce sanitary regulations, brought the people *en rapport* with the problem of the day, spread the knowledge that it is easier to prevent illness than to cure disease. But the final object of the antituberculosis campaign has not been accomplished; the loss of life from pulmonary tuberculosis is frightful and alarming. Investigations among the working classes and tenement population reveal appalling conditions, the white plague saps the nation's life blood. We know that among children there is a marked increase of sickness and death in every type of tuberculosis. What is the cause of failure? Why has the effort to eradicate consumption not been successful? Why have the unlimited power to do things, boundless resources, and lavish expenditure of money proved impotent to realize the aim and end?

The principal cause of failure is the fact that the main entrance gate for infection was left unguarded. While watching every possibility of communicating the disease from man to man the diseased cow was left undisturbed. A spitting man is feared like a poisonous serpent, but milk teeming with tubercle bacilli is admitted to house and nursery without hesitancy. The roller towel and common drinking cup were banished by legislative acts, the tuberculous cow retains the privilege to spread infection to animal and man until life's end.

Cattle tuberculosis is rapidly increasing, there is scarcely a dairy herd without a number of infected animals; it is an ever-growing menace, the undoubted cause of extensive infection and illness among young children—96 per cent. according to Behring's estimate. The health department of Boston estimates the percentage of tuberculosis animals producing the city's milk supply, to be from 20 to 25. New Haven, Rochester, and Washington found milk tests to give positive evidence of tuberculosis in 20 per cent. of the specimens. This list could be continued to include every city in the Union. Tuberculous milk is everywhere. Here is

the reason why tuberculosis persists unconquered. The antituberculosis campaign neglected to guard against this source of infection. The tuberculous cows and bovine bacillus have the entrée to the best houses. The rich man's children are not safer than his poor neighbor's, for certified milk does not assure milk from healthy cows, nor is milk the sole source of infection. Butter and even cheese provide a means to gain admission. In fact, a large percentage of the butter is the product of the milk sent to the creameries, being below the standard of the city's requirement of milk used for drinking.

It is high time for physicians and the people to recognize conditions as they are, that the mortality from tuberculosis remains the same, has increased among children; that there will and can be no improvement unless the antituberculosis crusade extends to the cow, unless the tuberculous cow is banished like the roller towel and tin cup, unless tuberculous milk is excluded from the market, whether pasteurized or in the raw state.

The protection of the tuberculous cow sacrifices the lives of thousands of children, because a few men, high in authority and position, decree that milk from healthy cows can be the privilege of only a chosen few; that the banishment of tuberculous cows from the dairy is impractical and unnecessary; that tuberculous cattle cannot be excluded from providing the milk supply of the masses, that the majority must be satisfied to feed their children with pasteurized milk from animals of a doubtful standard.

The security of pasteurized milk is fallacious. Pasteurized milk is not sterile; pasteurized milk always contains myriads of bacteria. The records of pasteurizing plants handling the milk in accordance with the regulations of the New York City Health Department show that pasteurization reduces the number of microorganisms to one-half—instead of one million to the cubic centimeter, there remain half of one million bacteria to each cubic centimeter of pasteurized milk. These rapidly increase and soon their number exceeds the original multitude. The writer does not decry the value of pasteurized milk. Pasteurization improves healthy milk, but it cannot and does not transform a diseased product into a healthy milk. Were this possible there would be no need of destroying meat from tuberculous cows—cooking would make it the equal of cuts from animals in the best of health.

By what means and methods can cattle tuberculosis be eradicated? Infected animals must be removed, and if possible destroyed. Cows which react to the tuberculin test, but not sufficiently to permit a positive diagnosis of tuberculosis must be separated and segregated from the diseased and the healthy animals. The tuberculin test is dependable, in experienced hands. The symptoms of reaction are temporary, lasting only two or three days.

As a safeguard and protection of the healthy cow, prophylactic vaccination has been used with great success. Behring, Theobald Smith, and McFadden obtained encouraging results. The most recent reports by Gilliland on the production of artificial immunity in cattle, carried on by the Live Stock Sanitary Board of Pennsylvania and by Castelli of Genoa, Italy, demonstrate that the inoculation of cattle against tuberculosis is successful beyond a doubt. In these experiments, living but modified cultures of the bovine bacillus were used. But vaccination with living bacilli is impractical for any but laboratory purposes. The writer has obtained identical results by a method which is simple, harmless and unobjectionable. He uses a bacillary emulsion prepared from dead cultures of both the bovine and human type of the tubercle bacillus, injected subcutaneously, three or four times, at weekly intervals. The injections cause neither local reaction nor general ill effects in the healthy animal. Infected animals show the temporary reaction from the tuberculin test. The protection by vaccination safeguards the healthy cow against infection by her stable companions. The advantages of vaccination to both farmer and consumer of milk are evident, the operation being simple, harmless, and effective, and it should be used on all cows proven healthy by the tuberculin test.

To rely upon the tuberculin test is futile, it gives no protection, and only shows whether the animal is healthy or ill at the time of test, and two or three months hence the animal may be in an advance stage of tuberculosis, unfit as a producer of milk. Such was the writer's personal experience; a fine herd of Jersey cows, kept under ideal conditions, tested and proved healthy by a competent veterinarian, contained three months later 70 per cent. reacters, some in an advanced stage of disease.

Thus annual or semi-annual tuberculin tests do not give assurance of milk from healthy cows. Recent attempt to compel annual tuberculin tests by legislative act encountered strong opposition and failed to pass; the farmer feared the destruction of diseased animals without adequate compensation.

An educational campaign, showing the advantages of protective vaccination, would, I believe, overcome the opposition and gain the support of the dairy interests in the crusade against bovine tuberculosis.

To destroy the diseased animals and leave the healthy ones to their fate, till the next annual inspection, is out of harmony with present-day methods of disease protection. But protective vaccination accomplishes much more than immunization of the cow and protection against her stable companions; it produces a supply of immunized milk, a remedy for patients infected by tuberculosis.

What are the functions and properties of immunized milk? Immunized milk possesses antibacterial qualities like the blood serum of animals which have been immunized; it is, in fact, a dilute antitoxic and bactericidal serum. In the course of disease, the body is stimulated by invading bacteria to produce specific protective substances, antibodies, agglutinins, precipitins, bacteriolysins, etc., to combat infection and neutralize the destructive effects of the pathogenic germs. The same effect is obtained by vaccination with living or dead bacteria; it causes specific antibodies in the body fluids and the condition known as active immunity. Besides the protection due to the body's own activity, immunity is created depending upon defense-substances produced by another organism; a resisting power against disease is conferred by artificially supplying the necessary specific antibodies.

These are the fundamental principles of protective vaccination, the basis for serum therapeutics, and an explanation of the action of immunized milk. Drinking the milk transmits the antibodies which pass through the intestinal mucous membrane into the general circulation. Thus immunized milk confers the same protection, the same immunity as inoculation with antitoxic and anti-bacterial serum. The presence of antibodies in the

milk of immunized animals has been doubted and denied, it being the general belief that antibodies were confined to the blood serum, and that furthermore they could not penetrate the intestinal mucous membrane, except in the very young animal.

This widely prevailing opinion was shared by a commission of scientists, appointed by the Department of Health of the City of New York, to examine and report upon the writer's work on immunization and immunized milk. Further investigation of immunized milk showed, however, that it contained specific antibodies, that feeding this milk caused their appearance in the other animals' blood. The experiments were conducted under supervision of Dr. W. H. Park, Director of the Bureau of Laboratories, Department of Health, City of New York. Dr. Park inoculated cows with dead cultures of the typhoid bacillus, whereupon the milk showed unmistakably the presence of the antibodies, specific to this bacillus. The typhoid bacillus was selected, because of the technical difficulties of determining the presence of antibodies of the tubercle bacillus. Feeding the milk to calves, five to six months old, caused the calves' blood to respond to the test for typhoid antibodies (Widal's agglutinin tests), thus proving their presence in the milk and passage into the blood by way of the intestinal canal. The chain of evidence was a complete one, inoculation with dead cultures, specific antibodies in milk and blood; feeding the milk followed by presence of antibodies in the blood which, prior to feeding, did not contain antibodies.

Experience with immunized milk proved it valuable as a prophylactic and remedy for tuberculosis. Immunized milk is not heralded as a "sure cure," but its properties can and do assist the body to combat the invading host and counteract the destructive effects of the bacterial products upon the organism. The use of immunized milk in various types of tuberculosis has given encouraging results. The writer has reported a number of cases of pulmonary tuberculosis, tuberculosis of the bones and joints, treated in institutions and private practice. Several patients who have facilities to keep goats, use the milk from immunized goats with splendid success. This is a simple and inexpensive method, deserving more extended adoption. Goat's milk is superior to the best cow's milk, and has neither objectionable odor nor taste.

Immunized milk is now being tested in other institutions, among them one of the tuberculosis hospitals of the City of New York (The Sea View Hospital in Staten Island). The results are reported to be good; the patients gain markedly in weight and show an improved general condition compared to the control cases.

This investigation is under the supervision of Dr. Fitzpatrick, a representative of the New York Department of Health. The investigation and results will be published by the Department. The writer's first publication of immunization by immunized milk (October 13, 1913) has induced others to use immunized milk and to inoculate cows for protection and for the production of immunized milk. The most recent report on immunized milk, was presented at the June meeting of the National Association for the study of tuberculosis at Seattle by Dr. Castelli, representing the University of Genoa, Italy, of which the following is an abstract:

We have applied successfully the method of vaccination against tuberculosis and we are able now to apply this vaccination on a large scale among human beings and animals and we have shown that we can even vaccinate pregnant women and animals and obtain products of conception showing features of complete immunization. More important still, acting on the knowledge that much of the tuberculosis infection in infancy is contracted through milk, which forms the principal element of infant diet, we concluded that if we vaccinated animals or vaccinated mothers, we would eliminate the principal source of infection of this disease. In our opinion, the baby that is made immune through the vaccination of the mother against a possible infection by the feeding of immunized milk, is a victim stolen from tuberculosis. We have succeeded in training a group of farmers in the Province of Genoa in the technique of immunization of animals and have demonstrated to them that the milk thus obtained does not change, either in taste nor in its nourishing qualities. The Faculty of Genoa is convinced that by applying to the prevention of tuberculosis all the means at our disposal, in less than fifty years from now we would accomplish in tuberculosis what Jenner has accomplished in smallpox. As part of a campaign which we had planned in Italy before the war, using the Boards of Health as agencies, we recommended the following program: (1) An extensive and regular use of serum diagnosis in hospitals, dispensaries, and private practice to secure earlier recognition of tuberculosis. (2) Advising vaccination of pregnant women. (3) Establishment of farms and dairies supplying immunized milk for exclusive use of children or adults showing evidences of tuberculosis. (4) Vaccination of pregnant cows, to secure immunized products of conception.

It will be noted that this report indorses the writer's claim that protective vaccination secures the cows complete immunity against bovine tuberculosis; that feeding babies with immunized milk eliminates the principal source of tuberculosis; that it is a remedy for every type and stage of tuberculosis. Noted authorities on tuberculosis advocate immunized milk for children with a tuberculous taint, enlarged glands, etc.

But the approval of a few is not sufficient, the cooperation of many is indispensable to spread the knowledge that immunized milk differs neither in taste nor in nourishing qualities from ordinary milk; that it is the best possible milk for everybody and for every purpose; that protective vaccination and the elimination of bovine tuberculosis are the basis, the fundamental necessity for the prevention of human tuberculosis.

Reduction of the number of infected cows will reduce the human death rate, misery, and suffering. A conservative estimate places the number of cows dying yearly from tuberculosis at one million, were they permitted to die a natural death, but they are killed before drawing the last gasp and served as prime beef. The number of human deaths from consumption and other forms of tuberculosis is about 200,000 per annum, and 1,500,000 are victims of the disease, partly or totally incapacitated, a burden to the State, to themselves, and to their families.

Can there be more convincing arguments for the need of exterminating bovine tuberculosis?

The remedy offers itself; will it be accepted? Must the tuberculosis problem repeat the experience of puerperal fever, duplicate the never-ending reproach recorded on the saddest page of the history of medicine? In 1846 Ignatz Semmelweiss, a young Viennese physician, announced his belief that puerperal fever was not a disease, but depended upon poison carried by the physician's fingers to the woman in childbed. He recommended washing of the accoucheur's hands with soap and chloride of lime, demonstrated that the use of this simple expedient reduced the frightful death rate of 15 per

cent. and higher to less than 2 per cent. Semmelweiss was bitterly opposed by the group of men, "who shape opinions," command "what is to be and not to be," and his plea was rejected. Ridiculed and scorned for his pains, he ended his life, a broken-hearted, disappointed man.

For more than forty years, millions of women were sacrificed upon an altar reared by envy, ill will, and prejudice, while performing the function of motherhood, leaving behind numberless motherless children. Forty years and longer lasted the controversy and debate, whether the cause of puerperal fever lodged in the air, originated in the woman's own body, or was due to the absorption by the blood of the woman's breast milk. Finally the method of Semmelweiss was accepted, physicians washed their hands, puerperal fever ceased to be.

Immunized milk presents another simple expedient, a sure and safe method to free man of the white plague's frightful burden, the means to rescue innumerable victims from suffering and death, preserve the health of infant and child and give it sound limbs and body, shielding it from the fate of the cripple, encased in braces and plaster.

It makes man the victor over disease, instead of being the victim. The exit of the tuberculous cow will mark the beginning of the end—the eradication of consumption, of tuberculosis of every type. The path of the disease is clear—from stable to nursery, from the milk to the child; tuberculous milk, tuberculous butter and cheese are the source of the pitable condition of many. A parody on our much vaunted advanced civilization.

To supply the city resident with immunized milk requires the facilities and organization of a modern dairy. A reputable concern has agreed to distribute a standard immunized milk at a slightly higher cost than a regular high grade milk, provided the demand is sufficient to justify the additional expense. I will personally supervise the herd's immunization, and to guard against error and substitution, each bottle will carry a special label, as suggested and permitted by the Department of Health. Dairies of other cities will supply immunized milk whenever a sufficient number of physicians advise its use.

When a cow or goat can be kept on or near the premises, a supply of immunized milk is easily obtained at the cost of ordinary milk, except for the first expense of immunization. Every tuberculosis suspect, every victim of consumption at every stage, the sufferer from every type of tuberculosis should be afforded the advantages of immunized milk; its use is never harmful but is always helpful.

The technique of immunization is that of the tuberculin test which must precede the injection of the bacillary emulsion, to determine the animal's health, the absence of tuberculosis. For the protection of the cow and to supply a healthy milk for every purpose, three to four subcutaneous injections of the vaccine are sufficient. Immunized milk intended to immunize the consumer, to serve as a prophylactic and a remedy, requires a larger quantity of antibodies. (This is the only type of immunized milk which will be supplied at the present time.) I usually give fifteen injections at weekly intervals, increasing doses of vaccine; after the fifteenth injection I constinue the last dose and inject every two to three weeks. This provides a milk of uniform strength, absolutely safe for the infant and the adult, the healthy and the ill, a food and a remedy.

Every infant fed with immunized milk saves a victim of tuberculosis; every sufferer from tuberculosis deprived of the aid of immunized milk is denied a possible chance to recover. Every public hospital should provide immunized milk. Every institution devoted to the treatment of tuberculosis is incomplete without a herd of immunized cows or goats.

Immunized milk combines the effect of protective vaccination as for smallpox and the serum therapy of diphtheria; it is the only specific remedy existant for tuberculosis. Immunized milk provides a continuous supply of specific antibodies in small quantities at frequent intervals, resembling the administration of calomel in fractional doses.

These are the facts of the tuberculosis problem, of protective vaccination, of the value and usefulness of immunized milk.

The preceding lines express my belief and conviction. The fate of immunized milk depends upon the support of the medical profession. If physicians accord their patients an opportunity to use it, are ready to aid my efforts to produce and supply immunized milk, make it available to all and every one, they can form an opinion based upon their own experience.

Farmers and dairies will supply immunized milk if it is demanded. Immunized milk will be demanded if physicians recommend and advise its use.

I trust that I have succeeded in convincing the reader that the use of immunized milk is desirable, yes a necessity to mankind. I will be glad to give further information to anyone interested in the production and use of immunized milk.

THE RESULTS OF SALVARSAN AND MERCURY IN EIGHTEEN CASES OF PRIMARY SYPHILIS.*

By JOHN CONSTAS, M.D.,

WASHINGTON, D. C.

ASSISTANT PROFESSOR OF OPERATIVE SURGERY AND ASSOCIATE IN GENITOURINARY DISEASES, GEORGETOWN UNIVERSITY; CHIEF GENITOURINARY SURGEON, WASHINGTON ASYLUM HOSPITAL.

Although the discovery of salvarsan is but recent, yet the literature upon this mighty agent is equal to if not greater than the literature on any other drug in the domain of medicine. No week passes that one cannot see an article in this or that medical journal on this treatment. Indeed, so much has been published and said about salvarsan that one feels a hesitation in advancing any opinion whatever.

Considering, however, the prevalence and severity of syphilis, this great scourge of humanity, and its complications and sequalæ, as well as the results following the administration of salvarsan, one cannot but feel enthusiastic and justified in adding an iota to what has already been published.

In spite of the severe complications and even deaths which have followed the administration of this drug, still it is the remedy par excellence for syphilis.

Out of 1,161 cases in which I have administered salvarsan or neosalvarsan, I have had not a single case of blindness, death, or any serious complica-

*Read before the District Medical Society, May, 1915.

tion, save some elevation of temperature, headache, vomiting occasionally, and a feeling of malaise. And as far as I know, neither death nor blindness has occurred from the administration of salvarsan in this city.

Since the object of this paper is to record the results of salvarsan in purely primary syphilis, I shall not touch upon the subject of syphilis in general, but will confine myself on the report of 18 cases of primary syphilis. I mean cases without any manifestation of secondary symptoms neither adenopathy nor other evidence in the mouth or thereabout.

The examination for spirochetes and the Wassermann test in all the 18 cases were made before and after the treatment by Drs. Nickols, Creggs, Reasoner, and Vedder of the Army Medical School of this city, to whom I am greatly indebted for their kind assistance in this matter. And now, with your kind indulgence, I will proceed with a report on my cases.

Case I.—J. S., aged 21, student, of unimportant past and family history, presented himself for treatment, Nov. 25, 1913. On examination I found a slight greenish abrasion, about one-quarter of an inch long, on the foreskin, posteriorly; Wassermann negative, but numerous *Treponemata pallida* were demonstrated on a dark field. There was no adenopathy, neither were there any subjective or objective symptoms. Last coitus Nov. 15 and 20, and Dec. 1, 1913. First intravenous injection of 0.06 gm. salvarsan on Dec. 12; second, Dec. 19; third, Dec. 28, 1913. In addition patient had eight intramuscular injections of 1 c.c. of 10 per cent. salicylate of mercury, weekly. March 25, 1914, Wassermann positive. In addition protiodide of mercury ¼ gr., three times a day for three weeks. May 20, Wassermann negative; Oct. 11, Wassermann negative; Feb. 3, 1915, Wassermann provocative test, negative.

Case II.—T. D., tailor, aged 23, family and past history good, save disease of childhood. Last sexual intercourse, Aug. 18, 1913. Appearance of lesion Aug. 29. Main sore on sulcus posteriorly, chancroidal in appearance and two small vesicles, one on the glans near the meatus and the other on the frenum. Glandular system normal. Wassermann positive. *Treponemata pallida* present. Sept. 5, intravenous injection of 0.06 gm. salvarsan was given and on the 13th of the same month he received another salvarsan 0.06 gm. by the same route. This was followed by intramuscular injections in the gluteal region of 1 c.c. of 10 per cent. salicylate of mercury for two months, which caused slight salivation. Jan. 13, 1914, Wassermann test negative; April 29, Wassermann test positive. On May 10, 0.06 gm. salvarsan was given; also on the 17th of the same month he received another injection of 0.09 gm. of neosalvarsan. This was followed by two months of protiodide of mercury by mouth. Oct. 27, Wassermann still positive. Patient is still under treatment.

Case III.—J. O. G., student, aged 22, family and past history unimportant. Date of infection, Jan. 31, 1914. Sores ranging from a vesicle to a small grayish ulcer all around sulcus and base of prepuce, none of them having the slightest resemblance to chancre. They rather suggested herpes. On March 5, Wassermann test positive; dark field; examination showed spirochetes. March 10, Wassermann positive. Dark field demonstrated abundance of *Treponemata pallida*. Same day salvarsan 0.06 gm. was administered intravenously, also another dose by the same route on March 22, followed by six intramuscular injections of salicylate of mercury, causing pronounced salivation. May 15, Wassermann test positive. May 17, 0.06 gm. salvarsan was administered June 14, Wassermann test negative; also on Nov. 7, Wassermann test negative.

Case IV.—J. M., merchant, aged 29; family history negative, past history bad. Typhoid fever when 19; also three attacks of gonorrhea. Date of exposure not definite. Sore on left side of sulcus ¼ of an inch in circumference; much indurated. June 1, 1913, Wassermann test positive. Spirochetes present. June 3, 0.06 gm. salvarsan was given, also a similar dose on June 10, both intravenously, followed by one month of mercurial injections. Because the sore persisted during the whole period of treatment, patient received another dose of neosalvarsan intramuscularly. On July 22, a few days after, sore disappeared. Nov. 11, Wassermann negative. April 29, 1914, a small round sore appeared on the left side of the glans penis. April 29, Wassermann negative. May 12, Wassermann + —. May 15 and 18 Wassermann provocative test negative. This time the sore disappeared.

Case V.—P. S., waiter, aged 28; family history negative. Patient was treated for chronic ulcer in the stomach when 25 years old. Glandular system normal. Date of infection, June 23, 1914, or therabouts. Large indurated sore occupying one-third of sulcus posteriorly. Patient first noticed the lesion three weeks after exposure. Wassermann positive, also numerous spirochetes were demonstrated in the dark field examination. Aug. 9, 0.06 gm. of salvarsan was administered intravenously, also another dose of 0.06 gm. on Aug. 18, followed by a period of two months mercurial injections. Nov. 9, Wassermann positive. Patient failed to appear since.

Case VI.—L. N., shoemaker, aged 24; family and past history unimportant. Date of infection, Oct. 12, 1913. A typical large indurated sore appeared two weeks after the exposure. No adenopathy save one or two superficial fermoral glands slightly enlarged. Wassermann negative but there was an abundance of *Treponemata pallida* in the dark field examination. Doses of 0.06 gm. salvarsan were administered intravenously, one on Nov. 11, 1913, and the second on Nov. 19, followed by ten injections, intramuscularly, of 1 c.c. of 10 per cent. salicylate of mercury. Feb. 27, 1914, Wassermann negative, patient went to Boston, and on Aug. 9, 1914, I was informed by his brother that patient had a slight cerebral hemorrhage which impaired his entire left side, also an eruption both of which the physician in attendance told his brother were due to syphilis.

Case VII.—C. J., waiter, aged 21; family history negative, patient has had two attacks of gonorrhea. Patient was last exposed Oct. 15, 1913. He first noticed a sore at the edge of the prepuce in the center; two weeks later Wassermann positive, spirochetes found. Dec. 3, 0.06 gm. of salvarsan was administered, followed by a period of three months of mercurial injection. March 19, 1914, patient's entire body, principally his arms and chest, was covered with an eruption of the squamous type; there were also two mucous patches, one on the left inner side of the lower lip and a large one on the left tonsil. This time two more injections of salvarsan were given intravenously, one on March 19, and the second on March 27, followed by six weeks' mercurial injections. July 12, Wassermann negative. July 14 and 18, Wassermann provocative test negative.

Case VIII.—W. G. R., professional man; father died of tuberculosis. Patient had chronic gonorrhea with a relapse at the time he sought treatment. Date of infection Oct. 21, 1913, appearance of lesion seven weeks later. Large indurated sore nearly ½ an inch in circumference on left side of sulcus and base of prepuce. No adenopathy. Jan. 1, 1914, Wassermann negative, dark field also negative. Jan. 8, Wassermann positive, dark field showed the greatest number of *Treponemata pallida* I had ever seen. Jan. 9, 0.06 gm. salvarsan was administered intravenously and a second dose followed on Jan. 15, followed by six intramuscular injections of 1 c.c. of 10 per cent salicylate of mercury. April 12, numerous white patches appeared in the mouth, principally on the inner side of the lips and fauces. Patient refused Wassermann test, feeling sure he was not cured and demanding further treatment. April 15, another 0.06 gm. salvarsan was administered, followed by mercurial injections for a period of a month. June 2, Wassermann negative. Patient failed to show up since.

I will now simply mention the results in the next ten cases, in which after the first and in some cases the second Wassermann test had been applied, the patient failed to respond for further observation.

Case IX.—J. R., professional man, date of infection, Oct. 20, 1913, received two 0.06 gm. salvarsan intravenously and one 0.09 gm. neosalvarsan intramuscularly, followed by two months of mercurial injections. Wassermann just recently made negative.

Case X.—A. S., cook, aged 33. Date of exposure, Dec. 1, 1913, Jan. 8 and Jan. 15, received one 0.06 gm. salvarsan and 0.09 gm. neosalvarsan, followed by three weeks mercurial injections. May 18, 1914, Wassermann negative.

Case XI.—J. S., aged 23, baker. Date of infection indefinite; Jan. 27, 1913, sore appeared. First intravenous injection of 0.06 gm. salvarsan, Feb. 2, 1914. Second intravenous injection of 0.09 neosalvarsan, Feb. 20. This was followed by a month of mercurial injections. April 21, Wassermann negative. June 24, provocative Wassermann negative.

Case XII.—J. A., aged 25. Restaurateur. Date of infection unknown. Primary lesion, Jan. 19, 1914. Received two 0.06 gm. intravenous injections of salvarsan followed by one month of mercurial injections. May 9, Wassermann negative.

Case XIII.—R. R. J., aged 37, hospital attendant. Date of exposure, Sept. 27, 1913, or thereabouts. Received 0.06 gm. salvarsan intravenously and one 0.09 gm. neosalvarsan one week apart, beginning Jan. 6, 1914, followed by a month of mercurial injections. April 30, Wassermann negative.

Case XIV.—P. S. N., aged 24; waiter. Date of infection Dec. 6, 1913. Appearance of primary lesion forty days later. March 9 and 16, 1914, two 0.06 gm. salvarsan were administered. No mercurial treatment. May 27, Wassermann negative.

Case XV.—I. B., hospital attendant, aged 22. Date of exposure, Feb. 20, 1914, March 15 and 23, two 0.06 gm. doses of salvarsan were given. June 5, Wassermann negative; July 6, Wassermann negative.

Case XVI.—H. S., aged 23, government clerk. Date of infection Feb. 1, 1914. Three intravenous injections were given; first, Feb. 18, second, Feb. 24, and third, April 2. No mercurial treatment was given. April 21, Wassermann negative.

Case XVII.—C. C., waiter, aged 31. Date of exposure, Feb. 20, 1914. March 13, 0.06 gm. was administered; also March 20, another 0.06 gm. salvarsan was given, both intravenously, followed by two weeks of mercurial injections of one c.c. of 10 per cent. of salicylate of mercury. July 3, Wassermann negative. Aug. 3, Wassermann provocative negative. March 12, 1915, Wassermann provocative negative; this patient had two provocative tests.

Case XVIII.—J. H., aged 27, government clerk. Date of infection not definite. Received first injection intravenously Jan. 17, 1914, second, Jan. 29. Also similar doses on April 2 and April 9. Lesion persisted until the last injection of salvarsan was administered. Patient received no mercurial treatment and has not been seen since.

In all the ten last mentioned cases both Wassermann and dark field examinations were made before treatment and all showed positive results.

From the foregoing report we deduct the following conclusion: that contrary to the prevalent opinion among the majority of physicians at home and abroad, the results of my experience in these cases force home upon me the conviction that from two to five salvarsan injections are sometimes necessary before one can finally pronounce a cure in primary syphilis. Still further do I advance the opinion that at least six Wassermann tests, together with one provocative test, should be made before one can with absolute security pronounce a patient cured.

Massachusetts Avenue.

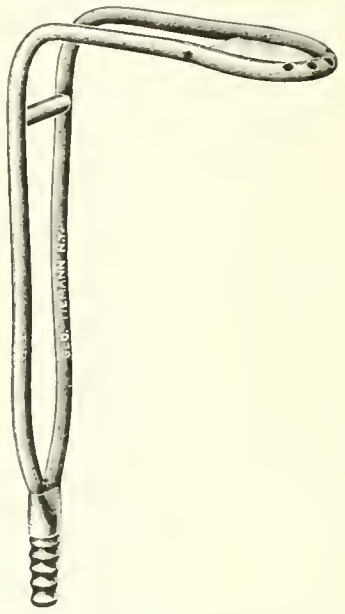
A SUCTION TONGUE DEPRESSOR.

By NORMAN EDWIN TITUS, M.D.,

NEW YORK.

In the course of adenotonsillectomies at St. Luke's Hospital, New York City, on the service of Dr. D. Bryson Delavan, Dr. A. P. Voislawsky, the associate attending surgeon, has been accustomed to use suction to remove the mucus and blood from the patient's mouth. For this a regular mouth sucker was used; the tube of which was fastened to the sheet over the patient by a towel clamp. An ordinary tongue depressor was also kept on the patient's chest most of the time. So it occurred to the writer to combine these two instruments.

The instrument illustrated herewith combines suction with a tongue depressor and has been found most advantageous in keeping the operative field free of blood and mucus. The holes are on the upper surface of the tube, so that no suction is applied to the tissue of the tongue itself. The uvula is sometimes caught, but no bad results have come from the effect of suction on this loose piece of tissue.



In view of the small caliber of the tube we have adopted the technique of having the operator immerse the suction tongue depressor in a basin of water as soon as the operation is completed. This point has been found sufficient to keep the tube free of clots which otherwise would easily form and make the instrument less effective.

Saint Luke's Hospital.

Medicolegal Notes.

Admissibility of Expert Evidence.—Where in an action by a tenant for injuries by escaping gas, the tenant testified as to her condition, and a physician testified that when he called at the tenant's apartment he noticed an odor of gas in the apartment, and that he found plaintiff suffering from chronic inflammation of the respiratory tract and irregular heart action, questions as to whether with reasonable certainty he could state the cause of the condition of plaintiff, and whether with reasonable certainty the condition was due to gas poisoning, were held to be improperly excluded.—Pincus v. Schlecter, New York Appellate Division, 153 N. Y. Supp. 67.

Revocation of License for Unprofessional Conduct.—A statute permitting the revocation of a physician's license for grossly immoral or unprofessional conduct is held not to be invalid, in Aiton v. Medical Examiners, L.R.A.1915A, 691, on the theory that what shall be regarded as unprofessional conduct is too uncertain to constitute a standard, since the language must be interpreted to mean that which is by general opinion considered to be grossly unprofessional because immoral or disreputable.

Basis of Hypothetical Questions.—The Missouri Supreme Court holds that, since an expert witness may give his opinion upon a hypothetical question as to the sanity of an accused person, and may also give his opinion based upon a personal examination of the accused, he may give an opinion having for a basis a hypothetical case, together with what he learns from such examination. Objection had been made, but was not sustained, that a hypothetical question cannot be combined with a physical examination; that the two must be kept separate.—State vs. Harris (Mo.), 177 S. W. 362.

EXPERIMENTAL YELLOW FEVER IN LABORATORY ANIMALS.

THE apparently successful transmission of yellow fever to laboratory animals has been reported by Marchoux and Simond, Thomas, Seidelin, Macfie, and Johnston. Marchoux and Simond in 1906 observed slight febrile reactions in chimpanzees which had been bitten by infected stegomyiæ. Thomas in 1907 and 1909 obtained febrile reactions and albuminuria in chimpanzees, and mild febrile reactions in rabbits and guinea-pigs. He experimented chiefly by means of infected mosquitos, and to a lesser extent by means of injections of blood from yellow fever cases. Seidelin in 1912 injected guinea-pigs with blood taken from a yellow fever patient on the fifth day of illness, and containing *Paraplasma flavigenum*. He found the parasites in the blood of two of the injected animals, but no marked febrile reaction was observed. Another experiment with blood taken from a patient on the seventh day of illness gave a negative result.

Macfie and Johnston in 1914 experimented on guinea-pigs, dogs, and rats. In guinea-pigs they obtained marked febrile reactions, and in some cases albuminuria, and in the blood they found paraplasma-like bodies. In dogs and rats positive results were likewise obtained as far as the examination of the blood was concerned, but a febrile reaction was observed in one rat only, and in none of the dogs.

Drs. Harold Seidelin and Andrew Connal of the School of Tropical Medicine, University of Liverpool, have published in a recent issue of the *Yellow Fever Bulletin* of the Liverpool School of Tropical Medicine a paper dealing with investigations and experiments made in the same direction, in Lagos, Nigeria, West Africa. In October, 1913, one of them obtained a strain of *P. flavigenum* from a yellow fever patient in Lagos, inoculating four guinea-pigs with blood drawn from a cubital vein. Since then they have carried on experiments with this strain, working mainly with guinea-pigs, which have been found very suitable. The guinea-pigs were carefully observed, records being kept of the temperatures and of the blood examinations, as well as of the post-mortem findings, with subsequent microscopical examinations. The guinea-pigs showed great variations in the way in which they reacted after infection. They showed considerable rises of temperature in some cases, and occasionally marked remissions; in fact, some of the temperature charts might be taken for charts from yellow fever in the human. A sudden drop of temperature occurred in several of these cases after four to nine days; and in such cases death, as a rule, took place at this stage, the post-mortem examinations showing alterations typical of yellow fever.

More or less marked, but rather irregular rises of temperature were observed in other cases, and death followed in one to two or three weeks after inoculation, a sudden drop of temperature just before the fatal issue often occurring also in this group. In other cases again, recovery took place, which was, so far as one could judge, often final, but sometimes only apparent, death supervening one or two months after inoculation. Emaciation and more or less pronounced albuminuria were the only abnormal conditions found post-mortem in these instances.

The conclusions reached by Seidelin and Connal as the result of their exhaustive experiments were as follows: The yellow fever parasite *Paraplasma flavigenum* has been transmitted to guinea-pigs and monkeys by direct inoculation of blood. The infection has been carried seriatim through twenty-three guinea-pigs. The peripheral blood of the infected animals contains forms of the parasite identical with those occurring in human blood in yellow fever. Various internal organs of the infected animals, particularly the lungs, contain elements which the investigators regard as division forms of *P. flavigenum*. No conclusive results have been obtained by mosquito experiments or by blood cultures.

Hitherto Seidelin has failed to prove the case for *Paraplasma flavigenum* as the pathogenic organism of yellow fever, and his work has not been regarded with much favor by students of tropical medicine. It is possible, however, that he may be right, and his work is at least worthy of respectful consideration.

IS OBSTETRICS A LOST ART?

IN a paper read before the Chicago Gynecological Society R. W. Holmes (*Surgery, Gynecology, and Obstetrics*, November, 1915) bitterly arraigns the profession for the apparently increasing tendency to resort to cesarean section under conditions which he does not consider to warrant such a severe operative procedure; and in the discussion of Holmes' paper, W. A. N. Dorland compares the operative furor for cesarean section at the present time to that seen in pelvic surgery some 15 or 20 years ago when ovaries were removed on all sorts of indications. Certainly many of us have heard reports of cases of abdominal, and especially of vaginal, cesarean section concerning which we have felt that the interests of mother and child would have been equally well if not better served by a less drastic measure; and we feel, therefore, that Holmes' paper is worthy of serious consideration.

With what might be called the old indications for cesarean section we are all familiar. To these have been gradually added other more or less cogent reasons for performing that operation, partly due to the fact that with the development of improved methods of aseptic technique abdominal section is more lightly undertaken than formerly, sometimes, unfortunately, by those not any too well qualified. Then again, the introduction of Dührssen's vaginal method of cesarean section seems to have stimulated a further small percentage of operators to employ this method of delivery in certain cases where less dangerous methods are entirely feasible. Holmes first considers the general aspects of the situation; then takes up in order the relation of obstructing tumors, eclampsia, and placenta previa to cesarean section. This is followed by an arraignment of those who do cesarean section on indefensible indications; and the author shows that a more profound knowledge of the obstetric art would have suggested a simpler way out of the real or imaginary difficulties in many cases where an entirely unwarrantable cesarean section has been done, and that too sometimes with disastrous consequences.

His conclusions are formulated as follows: (1) A contracted pelvis alone should be considered as the single, definitely permanent indication for cesarean section. (2) No cesarean section should be considered, unless the baby is in good condition, or unless section is the only resort. (3) Eclampsia, placenta previa, or other specious indications do not offer warranty for the operation unless there is some contributing obstetric anomaly. (4) Every woman with a relative indication (pelvic contraction) should be allowed to go into labor so that there may be a test of the actual cephalopelvic disproportion. During this test no vaginal examinations should be countenanced, but labor should be controlled by abdominal palpation and rectal examination. (5) It is neither wise nor expedient to permit a patient with an absolute indication or where cesarean section has previously been performed to enter labor. (6) A cesarean scar is a vulnerable point in the uterine wall, and is likely to rupture; therefore, a cesarean section once is a cesarean section always. The only exception worthy of consideration would be a multipara with soft, lax, or torn pelvic floor. (7) Cesarean sections have been performed on inordinately broadened indications which in many respects are not defensible. The indications should be restricted. (8) Obstetric manual dexterity has been compromised by the development of cesarean section. The beneficent results from obstetric procedures should be emphasized. (9) One who has a mortality of 5 or more per cent. for his cesarean sections should revise his indications—should use discrimination in his selection of cases.

While the author of the article quoted is at times too severe in his castigation of his fellow obstetricians, it is indubitably true that many cesarean sections have been performed upon questionable indications and possibly, as Holmes says, "many never will be reported, for there was no real justification for their performance."

CORRECTABLE PHYSICAL DEFECTS.

THE general prolongation of human life has given opportunity for bringing into relief a great many physical deficiencies and stigmata of degeneration which the previous shorter life snuffed out before development. For it must be remembered that all hereditary qualities or defects are not patent at birth, but keep continually cropping out thereafter; and the longer one lives the more of them will become patent. Although it is true that they all exist in the germ in a latent condition, yet in their latency they can give no concern except as transmissible characteristics. The large increase in the incidence of physical deficiencies with which we are now confronted is, then, rather a discovery than a new development, and is therefore more apparent than real. Besides the longer life and diagnostic refinements which brings these conditions forward, the apparent increase is the direct result of our rapid progress which requires of human beings the exercise of finer and better physical powers and those who do not have them soon become conspicuous.

Many of the physical defects are first discovered at school where the child is hampered in his progress because of his inability to comprehend or to be attentive or because of the presence of gross sensory deficiencies. The school medical inspection instituted in most educational organizations brings to light the cause of the backwardness of many of these children and allows their restoration to efficiency. Yet this inspection is at present very poorly developed, either because the time allotted for this work is too small or because the insufficiency of remuneration does not secure the best and the most conscientious work. Visual defects are perhaps the ones that cause the greatest amount of trouble to the school child, even though they are the most amenable to correction. High degrees of myopia or of astigmatism and juvenile cataracts may all be so severe as not only to be frequently mistaken for organic blindness, but actually to lead to it. The deficiencies include also ear diseases, dental caries, adenoids, nasal obstructions, tonsillar hypertrophy, gastrointestinal and parasitic conditions as well as the neuroses.

More recently the influence that the physical deficiencies exert upon the composition of the juvenile offender has aroused a great deal of interest. While it may be that the antisocial tendencies of a child may be but the untrained though normal atavistic tendencies of the human race, brought into especial emphasis because of parental neglect or other adverse environmental conditions, it is yet a fact that many of these delinquents are in the gross underdeveloped, undernourished, have many of the special physical defects, or are distinctly mentally feeble from the lack of potency of the special senses. Moreover, because of their physical weakness they are unable to take hold of the industrial occupations and are left to become the pauper, the vagrant, the prostitute, or the positively criminal.

Proper medical examination of these delinquents before they are improperly stamped as criminals would save many of them for future usefulness.

Chicago has made a remarkable advance in this respect by attaching to its juvenile courts a psychologist. The new children's court in the city of New York is a model in many respects, and will be in more when there is attached to it a physician experienced in this work, who can devote all his time to its development.

"Euthanasia" Again.

The newspapers devoted a great deal of their valuable space last week to a discussion of the justifiability of letting babies die when they are not built right. The occasion of the discussion was the loudly announced determination of a Chicago physician not to perform an operation which he seemed confident would save the life of a baby born with but one external ear and other defects and assumed also to be mentally deficient. From the newspaper accounts one gathers that this deformed child had an intestinal defect, and if this was the condition it is by no means certain that an operation would have resulted in prolonging life; it might even have cut it short. However, this is not the point. The discussion was simply a revival in a slightly modified form of the perennial dispute regarding the justifiability of so-called euthanasia. The discussion belongs to the silly season, for the question is a purely academic one and will remain so until the science of prognosis has advanced far beyond where it is now. The prognostic ability of the average, or even the better than average physician is about on a par with his diagnostic ability—and the autopsy room, according to Cabot, shows that that is hardly worth talking about. "The most exact calculator," says Emerson, "has no prescience that somewhat incalculable may not balk the very next moment," and this applies to the physician in equal measure with the weather forecaster. It is the duty of the physician to relieve pain, remove disease, and save life so far as in him lies the power. That he is justified in jeopardizing life to relieve intolerable agony is unquestioned, but to hold that he is permitted to take life or refuse to save life, if he can, because he thinks the life is not worth saving or cannot be saved, is pernicious. He does not know and cannot know that the life cannot be saved; nor can he say that an infant of a few days who is physically defective may not grow up to be a useful member of society—more useful, it may be, than some of those who would have condemned him, untried, to execution. In the specific instance above mentioned, if the physician thought the operation was not justified under the circumstances, he was right not to perform it, but the reason which he published to the world and Cook County for his abstention was not a good one.

The Dutchess County Health Association.

The fact is too well known to be insisted upon that the sick who are meagerly endowed with this world's goods are frequently inadequately or improperly cared for. Furthermore, it is obvious that good nursing is, at least, of equal importance with efficient medical service, while in many instances careful nursing is more than half the battle. It would be idle to dwell on the point that many lives that might have been useful to the community are lost for lack of care when sick, and this occurs, perhaps, more often in the country districts than in the cities. The Dutchess County (New York) Health Association has been formed to combat existing conditions and while the territory selected for investigation into the extent, care, and prevention of sickness under the auspices of the Committee on Hospitals of the New York State Charities' Aid Association and the Thomas Thompson Trust of Rhinebeck, N. Y., is of both urban and rural character, it is in fact more rural than urban. This inquiry is held to be the first systematic attempt to secure direct and detailed information concerning sickness in the home that has ever been made in the United States and the information acquired has been unique in its nature. The striking feature of this investigation has been that in the districts investigated there were found to be many instances of neglect, unnecessary suffering, and financial losses of large proportions, which can and should be checked. All of these undesirable and indefensible conditions, it was discovered, arose from the inadequate provisions existing for the care of the sick and the prevention of disease. As a result of the investigation it was revealed that out of eleven thousand people who lived in the district, sixteen hundred, or over 15 per cent., were seriously sick, and of the latter number more than six hundred, or 42 per cent., were inadequately cared for during their illness. Also the inquiry made evident the fact that in order to obtain the best results in the prosecution of a campaign to improve nursing conditions and the medical care of the sick, organized and coordinated efforts are essential. Space here is wanting to give in detail the comprehensive and workmanlike plan of campaign mapped out by those responsible for the formation of the Dutchess County Health Association, but it may be said that from a perusal of the report it appears to be lacking in no feature calculated to guarantee success. Preventive work will occupy a prominent place in the campaign and special attention will be given to the problems involved in the prevention of feeblemindedness, epilepsy, alcoholism, and tuberculosis, not by cooperating with the State and national agencies that are specializing along these lines, but by doing additional new work on its own initiative.

Traumatic Dementia Precox.

The somatic basis of dementia precox has frequently been debated, as well as the syndrome-like character of the affection, in virtue of which it might exist under a variety of circumstances. Among the systemic causes invoked to explain the nature of this affection are autointoxication, anomalies of internal secretion, and trauma. At a meeting last summer of the Hamburg Medical Society (*Berliner klinische Wochenschrift*, August 16) Weygandt described the case of a youth who fell from a scaffolding and suffered a contusion of the ribs. Soon afterward his mind seemed to fail and he threw himself from a balcony, sustaining a cranial injury. He now developed a condition highly suggestive of dementia precox, but passed at once into a cachectic state, ending in death. The autopsy finds were inconclusive. They were all microscopic and seemed to consist of old and recent miliary hemorrhages. Degenerative phenomena were in evidence and there were no evidences of inflammation. The author seems inclined to bring this case under the clinical domain of traumatic psychosis.

News of the Week.

To Aid Maimed and Blinded Soldiers—There has recently been founded in France, under the patronage of President Poincaré, a Union of Neutral Colonies, which has for its object the assisting of blinded and maimed soldiers, and at a meeting on November 16, at which Ambassador Sharp presided, an American Colony was organized. It is estimated that each soldier helped will cost the Union from four to five francs a day, and that it will be necessary to continue the assistance for six months at least. The Union has thus far an annual revenue of $4,000, of which $1,200 has been subscribed by Americans.

Hospital Ship Sunk.—The British Hospital ship Anglia, crossing the Channel from France with nearly 400 wounded soldiers on board, struck a mine when three miles off shore and sank in a few minutes. Eighty-five soldiers were reported drowned, as well as some of the nurses and crew.

Dr. Cecile Lenore Greil, one of the survivors of the *Ancona* massacre, is a graduate of the New York Eclectic College in 1910, and was formerly assistant neurologist to Mt. Sinai Dispensary in this city.

New York City Death Rate.—During the week ending November 13 there occurred in New York City 1,324 deaths, giving a death rate of 12.34 per thousand, against a total of 1,276 deaths during the corresponding week of last year, when the rate was 12.54. The most noteworthy features of the mortality record for the week were the decrease in the number of deaths reported from acute infectious diseases and in the increase in those from diarrheal and respiratory diseases. The mortality of children under one year of age was considerably greater than that of last year, 232 as against 183. The death rate for the first forty-six weeks of the year, based upon a revised estimate of the population, was 13.59 per thousand, as against a rate of 13.75 per thousand for the same period of 1914, a decrease of 0.16 of a point. If this decrease be maintained during the remaining weeks of the year there will be approximately 885 fewer deaths during the entire year than during 1914.

Chicago Death Rate.—The death rate in Chicago for the week ending November 13 was 12.4 per thousand, as against 11.7 for the corresponding week of 1914, the total number of deaths being 581 and 537, respectively. There was only one death from typhoid fever, while diphtheria caused 13, measles 4, tuberculosis 74, pneumonia 51, and infantile diarrhea 44.

To Study Microbes.—A course of lectures on "The Haunts and Habits of Microbes" is to be given to the employees of the Department of Health in the laboratory of the Bellevue Hospital Medical College on alternate Saturdays from November 20 until next May, under the direction of Dr. William H. Park, director of the Research Laboratory. It is thought that such a course will serve to familiarize the sanitary and food inspectors of the department with some of the advanced scientific aspects of their work.

Diagnostic Wassermann Clinic.—The Department of Health of New York calls attention to the establishment of a Wassermann Diagnostic Clinic at the Bronx Borough Office, 3725 Third Avenue, where the drawing of blood for the complement-fixation tests for syphilis and gonorrhea, the taking of smears, etc., will be carried out. Physicians who desire to avail themselves of the services offered are urged to refer their Bronx cases to this office. The hours are from 11 a.m. to 1 p.m. daily, Sundays and holidays excepted.

Bureau of Child Hygiene.—At a conference in New York on November 17 on "What the City Does for the Child, and What the City Should Do" Dr. Josephine Baker, director of the Bureau of Child Hygiene of the Department of Health, stated that 60,000 babies annually were cared for by the bureau, and that this care began as soon as the child was born, a trained nurse being sent out on each case immediately after the birth certificate was received. The death rate among babies in New York, Dr. Baker said, had been reduced to 95 per thousand, the lowest mortality rate in the State, and the lowest rate among the ten big cities of the country.

Clearing House for Feeble-Minded.—The New York State Board of Charities advocates the establishment by the State of a clearing-house for the mentally defective, to determine the special treatment suitable in each case. The Board favors the enlargement of the present State institutions for the feeble-minded to a capacity of 2,500, the establishment of three new institutions, and State control of the New York City institution for the feeble-minded on Randall's Island.

Physicians Warned.—The filing of several death certificates in cases of tuberculosis which had not previously been reported has led the city health officer of Portland, Ore., to notify physicians that they are subject to punishment under both city ordinance and State law for failure to report any case of contagious disease.

Anthrax Case.—For the third time in three months a fatal case of anthrax has been reported in New York, an unusual feature of the case being that none of the three patients was in a direct manner liable to the disease, by employment or otherwise. The last victim was a young woman who up to the time of her illness was employed in a candy factory. It has been suggested that in this instance the disease may have been contracted from a piece of cheap fur worn about the neck.

Centenarian Dead.—Mrs. Emma Cable of Paramus, N. J., died at her home recently at the age of 101 years and 10 months.

Orders Tonsils Removed.—Justice Ryan of the Brooklyn Children's Court on November 17 decided that the Board of Education had the right to compel the removal of physical conditions which retard a school child's mental progress, and, therefore, instructed the parents of a child who had been brought before him on a charge of truancy to submit to the demand of the Board that the child's tonsils be removed. The fact that the child's tonsils were diseased had been given by the parents as an excuse for his delinquency.

Christmas Seals.—The State Charities Aid Association of New York has distributed throughout the State 15,000,000 Red Cross Christmas seals, the proceeds of the sale of which will be devoted to tuberculosis work as usual.

Blockley Association.—The twenty-ninth annual banquet of the Association of Blockley (Philadelphia General Hospital) ex-Resident and Resident Physicians, was held at the Hotel Adelphia, Philadelphia, on November 13. Dr. Charles S. Potts presided, and addresses were made by Dr. Oscar H. Allis, Dr. Daniel L. Bertolette, Dr. David Riesman, Dr. R. C. Rosenberger, and others. The fol-

lowing officers were chosen for the ensuing year: President, Dr. B. Franklin Stahl; First Vice-President, Dr. J. Chalmers Da Costa; Second Vice-President, Dr. David Riesman; Secretary, Treasurer, Dr. David R. Stone.

Surgeon's Degree.—The American College of Surgeons, which held its fourth convocation in Boston recently, has approved the desire expressed by many surgeons for a distinct degree which would differentiate the surgical and medical branches of the profession. The fellowship pledge just adopted by the college reads as follows: "Recognizing that the American College of Surgeons seeks to develop, exemplify and enforce the highest traditions of our calling, I hereby pledge myself, as a condition of fellowship in the college, to live in strict accordance with all its principles, declarations, and regulations. In particular I pledge myself to pursue the practice of surgery with thorough self-restraint and to place the welfare of my patients above all else; to render willing help to my colleagues and to give freely my services to the needy. Moreover, I pledge myself to shun unwarranted publicity, dishonest money-seeking, and commercialism as disgraceful to our profession; to refuse utterly all secret money trades with consultants and practitioners; to make by fees commensurate with the services rendered and with the patient's rights, and to avoid discrediting my associates by taking unwarranted compensation."

Salvarsan Released.—The appeal of the American Government to Great Britain for the release of fifteen cases of salvarsan shipped from Germany to the United States and held by Great Britain has been favorably considered, and the drug will be forwarded without delay. It is hoped that this shipment will be sufficient to meet the demand for the drug until it can be manufactured here. France, it is said, protested against the granting of the appeal on the ground that it could supply the need with salvarsan of its own manufacture, and it is possible that further supplies can be obtained from that country.

Clubhouse for Nurses.—The corner-stone of a new Central Club for Nurses, connected with the Young Women's Christian Association, on East Forty-fifth street, New York, was laid on November 17. The building will be thirteen stories high and will contain 218 single and eighteen double rooms, besides a sewing room, dispensary, library, offices, rest rooms, reception rooms, tea room, cafeteria, and roof garden.

Charitable Bequests.—By the will of the late Julius S. Hotchkiss of New Haven, Conn., the New Haven Hospital receives a legacy of $100,000.

The Delaware Hospital of Wilmington, Del., receives a residuary bequest of $15,000 under the will of the late James G. Hendrickson of Philadelphia.

Harvey Society.—The third lecture of the series will be given at the New York Academy of Medicine, 17 West Forty-third street, on Saturday evening, November 27, 1915, at 8.30 p.m., by Dr. Eugene F. Du Bois, Cornell University. Subject, "The Respiration Calorimeter in Clinical Medicine."

Personals.—Dr. David W. Cheever of Boston, Dr. Wilfred T. Grenfell of Laborador, Dr. Stephen Smith of New York, and Dr. Lewis McL. Tiffany of Baltimore were elected honorary fellows of the American College of Surgeons at its recent meeting.

Dr. Leo Loeb has been appointed professor of comparative pathology in the Medical School of Washington University, St. Louis.

Dr. James G. Cumming of Ann Arbor, Mich., has been appointed director of the Bureau of Communicable Diseases of California.

Degrees Conferred.—The University of Pittsburgh conferred the degree of doctor of laws on Dr. John W. Williams, dean of the Johns Hopkins University Medical School, Dr. Barton Cooke Hirst, professor of obstetrics in the University of Pennsylvania, and Dr. Walter W. Chipman, professor of obstetrics and gynecology in McGill University, on the occasion of the dedication of the Elizabeth Steel Magee Hospital in Pittsburgh recently.

Dr. Henry Charlton Bastian of London, emeritus professor of medicine and clinical medicine at the University of London, consulting physician to the University College Hospital and to the National Hospital for Paralyzed and Epileptics, died on November 18, aged 78 years. Dr. Bastian was a believer in the theory that life is a form of energy which can arise spontaneously, and considered that his experiments, which he published in 1870, proved conclusively that life can arise from inorganic material. The truth of his observations, however, was contested by both Huxley and Tyndall.

Tuberculosis Conference.—At the joint meeting of the North Atlantic Tuberculosis Conference and the New York State Tuberculosis Conference at Albany on November 4, telegrams were read announcing that the voters of five counties in New York had approved plans to erect tuberculosis hospitals. Thirty-five counties in the State are now provided with hospitals for tuberculous patients, or have definitely decided to build them. Nineteen such hospitals are already in operation and three more are in course of construction. The movement against tuberculosis has been more widespread in New York than in any other State. Addresses were made at the conference by Governor Whitman, Dr. H. M. Biggs, State Commissioner of Health, Dr. John B. Andrews, secretary of the Association for Labor Legislation, who advocated the establishment of a State health insurance system, Dr. Frederick L. Hoffman, who spoke on "Tuberculosis as an Industrial Disease," Dr. Haven Emerson, Commissioner of Health of New York City, and Dr. Victor G. Heiser, formerly director of the Department of Health of the Philippine Islands.

Prevention of Blindness.—Ex-President Taft, Mr. Joseph H. Choate, Prof. G. E. de Schweinitz, and Mr. Edward M. Cleve were the speakers at the meeting of the National Committee for the Prevention of Blindness at the New York Academy of Medicine on November 4. Mr. Taft expressed his belief that the energy and knowledge which had rid the Panama Canal Zone of yellow fever and malaria, and within a few months has put a stop to the ravages of typhus fever in Serbia, would be able to wipe out to a large extent the proportion of blindness from preventable causes in this country. Mr. Van Cleve told of the campaign which is now being waged against ophthalmia neonatorum through lectures illustrated by lantern slides.

Covered Garbage Carts.—Following a conference on November 5, with 300 contractors employed by New York City to dispose of ashes, garbage, and other refuse, Commissioner of Health Emerson stated that after January 1, 1916, no permits would be issued for the use of uncovered carts. The wagons used by the Department of Street Cleaning in removing ashes and garbage are already provided with covers, and there will no longer be any discrimination between this Department and the contractors.

Spurious Drugs.—The Bureau of Chemistry, Department of Agriculture, has recently issued a circular letter calling attention to the fact that considerable quantities of spurious aspirin and neosalvarsan are being peddled about the country in a way that makes it difficult to find interstate shipments. The spurious aspirin is a mixture of either calcium acid phosphate and starch, cream of tartar, and citric acid with some alum, or milk, sugar, starch, and calcium acid phosphates. The so-called neosalvarsan consists of common salt with naphthol yellow. While the Department of Health of New York City, in accordance with this warning, has notified the drug trade to be on its guard against these vicious frauds, it is impossible to protect the medical profession from unscrupulous druggists, and it is suggested that physicians who have any reason to believe that substitution has been practised in the compounding of prescriptions, send a sample of the medicine together with a copy of the prescription to the Department for examination.

Leprosy in Boston.—The Boston City Health Department announced on November 6 that a young man who had been afflicted with leprosy for at least seven months had been working as a dishwasher in a small west end restaurant. The patient, a Greek, had received treatment at a hospital for several weeks before the nature of his ailment was recognized. The case has been reported in order to emphasize the need of legislation giving the Health Board power to license all persons handling food.

Milk Inspection.—The quarterly meeting of the Milk Committee of the Westchester County (N. Y.) Medical Society was held at the Hotel Gramatan, Bronxville, on November 5. This board employs inspectors to examine the various dairies in Westchester County and no milk is certified until the dairy has complied with the requirements of the board.

Change Hospital Name.—By a recent order of the Supreme Court the Red Cross Hospital on Central Park West, New York, will be permitted to change its name to the Park Hospital. The institution was founded in 1894 as a branch of the National Red Cross, but it is felt now that the change in name will give it a wider scope and permit of greater accomplishments.

Medical Society Elections.—The Southern Medical Association, at its annual meeting held in Dallas, Texas, on November 10 and 11, elected the following officers: *President*, Dr. Robert Wilson, F. Taylor, Fort Worth; and Dr. Guy Hunter, Balti- Jr., Charlotte, N. C.; *Vice-Presidents*, Dr. Coleman more; *Secretary-Treasurer*, Dr. Seale Harris, Birmingham, Ala. Atlanta was chosen as the meeting place in 1916.

Medical Society of the County of New York: At the annual meeting of this society, held on Monday evening of this week, there was a spirited contest over the election of the first vice-president and of the delegates to the State Society, the contest being made by members of the society belonging to the Federation of Medical Economic Leagues. The latter were defeated, the election resulting as follows: *President*, Dr. Frederic E. Sondern; *First Vice-President*, Dr. J. Bentley Squier; *Second Vice-President*, Dr. Charles H. Peck; *Secretary*, Dr. John Van Doren Young; *Assistant Secretary*, Dr. Daniel S. Dougherty; *Treasurer*, Dr. Charles H. Richardson; *Censors*, Drs. Howard C. Taylor, Willy Meyer, Floyd M. Crandall; *Delegates to the Medical Society of the State of New York*, Drs. Alexander Lyle, Orrin Sage Wightman, Ralph Waldo, Daniel S. Dougherty, Ernest E. Smith, Brooks H. Wells, John Van Doren Young, Harold Hays, J. Bentley Squier, Lewis F. Frissell, Ward B. Hoag, George W. Kosmak, Nathan E. Brill, and Calvin S. May.

American College of Surgeons: Annual meeting at Boston on October 30. Officers elected: *President*, Dr. J. M. T. Finney, Baltimore; *Vice-Presidents*, Dr. W. W. Chipman, Montreal, and Dr. Rudolph Matas, New Orleans; *Treasurer*, Dr. Albert J. Ochsner, Chicago; *Secretary*, Dr. Franklin H. Martin, Chicago. The fund of the society was increased by about $100,000, bringing the total amount to nearly half a million, with which it is purposed to establish a great medical library and museum.

Minnesota Academy of Ophthalmology and Oto-Laryngology: Annual meeting at St. Paul in October. Officers elected: *President*, Dr. Thomas McDavitt, St. Paul; *First Vice-President*, Dr. John M. Robinson, Duluth; *Second Vice-President*, Dr. John A. Watson, Minneapolis; *Secretary-Treasurer*, Dr. John Morse, Minneapolis.

Charlestown (Mass.) Medical Society: Annual meeting on October 18. Officers elected: *President*, Dr. Pramath N. Roy; *Vice-President*, Dr. Nelson M. Wood; *Secretary*, Dr. Joseph B. Lyons; *Treasurer*, Dr. Francis L. Magurn.

New Haven County (Conn.) Medical Society: 131st annual meeting at Waterbury on October 28. Officers elected: *President*, Dr. William W. F. Verdi, New Haven; *Vice-President*, Dr. Frederick G. Graves, Waterbury; *Clerk*, Dr. Willis E. Hartshorn, New Haven.

National Society of Keep Wells.—This society, which has its headquarters in Washington, D. C., has plainly indicated its object in the name it has selected. Meetings are held frequently and at these physicians are invited to speak on the preservation of health in popular fashion. These familiar talks will then be published by the society so that their influence may be more extensive and permanent.

Obituary Notes.—Dr. Rush W. Kimball of Norwich, Conn., a graduate of the Long Island College Hospital, Brooklyn, N. Y., in 1890, medical examiner of New London County, visiting surgeon to the William W. Backus Hospital, and a member of the American Medical Association and the Connecticut State and New London County Medical Societies, died at his home on November 15, aged 52 years.

Dr. Hermann E. Hasse of Santa Monica, Cal., and formerly of Milwaukee, Wis., a graduate of the University of Würzburg, Bavaria, Germany, in 1861, a veteran of the Civil War, and a botanist of international authority, died at his home on October 30, aged 79 years.

Dr. Frank D. Harter of Grand Rapids, Mich., a graduate of the Chicago Homeopathic Medical College in 1900, died at his home from blood poisoning following an ulceration of a tooth, after a short illness, on November 1, aged 43 years.

Dr. Michael J. Nonney of Manawa, Wis., a graduate of the Milwaukee Medical College in 1911, and a member of the State Medical Society of Wisconsin and the Waupaca County Medical Society, died suddenly in his office, on October 22, aged 39 years.

Dr. William Wallace Chisholm, a graduate of Hahnemann Hospital and College of Philadelphia, with class of 1915, and an interne at the Hospital, died on October 29.

DR. FRANCIS DELAFIELD.*

IN MEMORIAM.

By THEODORE C. JANEWAY, M.D.,

BALTIMORE, MD.

As I look about me and see so many of you who, twenty years ago, sat with me in the big lecture room at Fifty-ninth Street, I know that the subject of this evening's discussion brings instinctively before your minds, as it always does before mine, the picture of that four o'clock lecture and the tall, calm figure of the man who gave us our first fundamental concepts of renal disease. Dr. Francis Delafield made original contributions to knowledge in many aspects of pathology and clinical medicine, but to none did he devote so much labor as to the study of diseases of the kidneys, and on none did he so impress the personal point of view which grew out of that labor. Our nomenclature may change again and again, differing interpretations of inflammation may come and go, new methods of investigation in the living will alter the emphasis and determine the interest of succeeding generations, but none of us can ever forget the basic facts of morbid anatomy and of the association of ante-mortem pictures with post-mortem lesions, whose clear delineation we, in New York City, owe to Francis Delafield more than to any other man. In this work, as in all that he did in medicine, he followed in the best tradition of the first great student of disease of the kidney, Richard Bright himself. He followed, but not blindly, insisting on seeing every step with his own eyes, both during the illness of the patient and when the body was brought to the autopsy room. Nor did he stop there. The morbid anatomy of Bright was a gross anatomy; Dr. Delafield's study was not finished until the tissues had been cut by his own hand and subjected to the most careful scrutiny under the microscope. No memory of him is more fixed in my mind than the occasional glimpse through the half-open door of his little room under the big amphitheatre, where he sat by his microtome cutting his own sections. In these days of enthusiasm for experimental investigation as contrasted with morphological, some would tell us that the professor of medicine who works in his laboratory with his own hands is a new figure. Such men can never have passed that half-open door as I did, nor have tiptoed their way fearsomely among the specimen jars of a father's workshop in such a home as I grew up in. There is no new figure in medicine. Galen himself was a laboratory clinician. Only the laboratory has changed, and we, in our day, may attack new problems with new tools, because those who have gone before have solved so many of the old problems with other tools.

Dr. Delafield was a frequent contributor to medical periodicals over a long term of years. His first publication appeared in 1868 in the *Medical News*. Between this and 1904, a term of thirty-six years, he published eighty-two articles. His descriptions of broncho-pneumonia, of organizing pneumonia, "lobar pneumonia with the production of new connective tissue," as he called it, of meningitis, of emphysema, of non-obstructive jaundice, being especially noteworthy, in addition to his studies of nephritis. Besides all this, he published with Stillman, "A Manual of Physical Diagnosis," in 1878, contributed to the International Encyclopædia of Surgery in 1881, the article on "Pyæmia and Allied Conditions" and to Pepper's System of Medicine, and its successor, "The Twentieth Century Practice of Medicine," the sections on Diseases of the Kidney. His lectures on the practice of medicine are familiar to you all. But his larger books show how pre-eminently a laboratory clinician he was. In 1872 his "Handbook of Post-mortem Examinations and of Morbid Anatomy" appeared, a volume of 376 pages. In 1885 it was followed by the first edition of Delafield and Prudden's "Handbook of Pathological Anatomy and Histology," with 575 pages. Delafield and Prudden still remains the standard American text-book of pathological anatomy, and in 1914 reached its tenth edition, having grown to 1116 pages. Besides all this, between 1878 and 1891 he published his illustrated "Studies in Pathological Anatomy," a lasting monument to his industry and his attainments as a pathologist.

As a teacher, his memory is still fresh with most of us. Speculation had no place in his lectures or clinics. To present facts in the fewest words was his invariable method. He never resorted to any of the tricks of the lecturer to stimulate interest, nor could one imagine him descending to facetiousness. He cared not for popularity. His very bearing was instinct with dignity and reserve. We often thought there was no appreciation of the lighter side of life behind that reserve until, one day, we caught the twinkle in those deep-set eyes and knew that we were wrong. Nothing is more characteristic of his modesty than his motive in promoting the organization of the Association of American Physicians, of which he was the first president. This motive, he said, was that there might be a medical society of which no one would know who was president, and no one would care.

Gentlemen, when Francis Delafield passed away last summer, in his seventy-fourth year, New York City lost one of the really great figures which it has contributed to American medicine. The profession of New York should cherish his memory by following his example:—to care not for fame, but for fact; to spare no labor in the ascertainment of fact; to use to the full each new method which will put us in possession of new facts; to impart those facts in language which shall be unequivocal; to face facts with uncompromising honesty to the reality outside ourselves and to our own mental integrity, and to face situations with unswerving fidelity to others. In one thing only would I have you diverge from his precepts,—I would have you not cease to remember, nor forget to honor the name of Francis Delafield.

*Read at a meeting of the New York Academy of Medicine, November 4, 1915.

Public Health School.—Plans for a School of Sanitary Science and Public Health are now being prepared by the Department of Extension Teaching at Columbia University, and it is hoped that courses may be offered during 1916-17. Graduates of the school will be eligible for positions in the State and municipal service as public health laboratory workers, public health statisticians, sanitary engineers, medical officers of health, and administrative officers or commissioners of health. It is proposed to have the course extend over two years, and to require a certain amount of preliminary education. Those who complete the course will be given a certificate from the Administrative Board of the Extension Teaching Department.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

FATIGUE—GUNSHOT WOUNDS OF PERIPHERAL NERVES, MEDICAL AND SURGICAL ASPECTS—INTESTINAL STASIS—PTOSIS AND STASIS—NOVO-ARSENOBENZOL, A DANGER—BRIGHTON SOCIETY, PRESIDENTIAL ADDRESS ON OBSTRUCTION.

LONDON, November 6, 1915.

FATIGUE after work or exercise is a natural condition—not as some seem to think injurious and so to be prevented. It is not merely a normal physiological process, but is probably essential to the health of the body. So long as repair keeps pace with waste all goes well, but let this fail and injurious fatigue sets in leading to destruction—a condition which may be brought about not only through excessive or too prolonged exertion, but by inadequate rest. Besides this the accumulation of toxic results of tissue changes from interruption or diminution of excretory action must be reckoned with. Any interference with the normal functions by want of ventilation or by atmospheric toxins will lead to more rapid development of the condition of fatigue; as will also any failure to distribute proper rest intervals throughout the working day so as to ensure the recovery of the tissues before they have become thoroughly exhausted, which condition would lead to great increase of ultimate fatigue. To test the rapidity of response to a stimulus eight women in the printing trade were experimented on, the reaction times being determined at the beginning and end of the day's work. Four out of the eight took less time to respond in the evening than the morning, though in several instances this was not so and in some the reverse occurred. As to the effect of daily work on fatigue it was found that at the beginning of the work the response was quicker in the evening than morning, but on successive days the evening became, relatively to the morning, slower and slower, until on Friday the time in the evening was considerably greater than in the corresponding morning. Progressive habituation to the test seemed to affect the result. It appeared as if men gradually became less able to withstand the wear and tear of a day's work. In women the results were less regular, but there was some evidence of considerable fatigue on Friday. The foregoing notes relate to muscular fatigue. Mental, as we call it, is made more obscure and we have no definite knowledge about it. To call it a disturbance of coordination explains little, if any, more than to say it seems due to a lack of attention or an inability to concentrate thought. Some of these points have been suggested by a report to the Home Secretary by Dr. Stanley Kent.

The Medical Society of London is engaged in a discussion on gunshot wounds of the peripheral nerves. It was opened by Dr. Wilfred Harris, who considered (*a*) the diagnosis and localization of the injury, (*b*) the prognosis, especially as to the question whether operative treatment were required. He laid down that there should be an accurate history of the wound or wounds and their effects, a methodical examination of both the motor and sensory paralysis to determine if it agreed with the anatomical distribution of a nerve or nerves, or a portion of a plexus, or if it resembled phenomena of hysteria. Careful charts of sensory loss were more important than the presence of complete muscular paralysis with reaction of degeneration, in estimating the severity of injury to a mixed nerve. In testing sensation the stimuli used were tests of different degrees of conductivity of the nerve, not of different systems of fibers. In secondary suture of nerve, recovery of sensation might begin within a few days. Variations of sensibility had to be allowed for, as differences might be noticed from day to day, according to whether the limb was warm or cold.

Mr. Wilfred Trotter submitted a paper on the surgical aspect of the question. He held that experience at present could not give a definite estimate of results. Restoration of a peripheral nerve presented problems in plastic surgery of a special kind. Interruption of a nerve left a permanent defect which could not be compensated by any other mechanism. Restoration of a nerve to its normal anatomical continuity was not a guarantee of recovery. An incomplete lesion or an incomplete recovery of a nerve might be more disabling than a total loss of function. He divided these injuries into (*a*) complete typical lesions; (*b*) mixed lesions with complete division of some trunks or parts of trunks and incomplete division of others; (*c*) incomplete lesions without pain, such as bruising, laceration, scarring, pressure; (*d*) incomplete lesions with pain; (*e*) pure pressure lesions, as by bone or foreign body. As to treatment, isolation of the central nervous system had been more and more insisted on in recent years and the facts of cerebral surgery showed the importance of the isolating mechanisms, *e.g.* ready reformation of the dura after removal; impossibility of draining cerebrospinal fluid into the subcutaneous tissues. Division of a nerve brought about a complicated reaction between the central end and surrounding tissues and regeneration depended on this: where reactions could not occur, as in the spinal cord, no regeneration took place; where they could occur fibrosis might interfere. A regeneration which involved a reaction between nerve and tissue was apt to set up irritation of the nerve rendering it hypersensitive, as in the so-called amputation neuroma, which was a necessary sequence of nerve section. When great deficiencies of nerve have to be closed two plans have been tried: (1) implanting both ends in an adjacent trunk; (2) filling the gap with one or more lengths of a large cutaneous nerve. The most exact coaptation of sutured ends must be effected and the portion of nerve insulated from surrounding tissue. This can be done by stitching a tube of subcutaneous fat closely round the nerve and fixing it to its sheath. The strictest asepsis must be ensured. If resection be decided against the nerve must be freed from scar or other pressure and wrapped in fat. Muscular relaxation must be secured both before and after operation.

At the Royal Society of Medicine Prof. A. Keith introduced the subject of intestinal stasis in reference to certain *x*-ray appearances. In the dissecting room of the London hospital, about the time of Lane and Starling's researches, his attention was drawn to such problems by the number of cases of displacement (towards the pelvis) of abdominal viscera and he concluded that the muscles in the abdominal wall are the chief agents in maintaining the viscera in position when the person is standing up and these muscles are called into action by reflexes arising when the erect position is assumed. While the mesenteries may act as ligaments, they only do so when muscular support has been overcome. Re-

cent examination of a series of colons which had been excised showed that stasis and ptosis may be due to the same lesion. He based an explanation on Sherrington's discovery that stimulation of the splanchnic nerves threw the abdominal muscles into tonic contraction. The intramuscular nerve plexus and peritoneal covering were both visibly altered in most specimens he had examined.

Dr. A. F. Hertz agreed for the most part with Dr. Keith, though he thought the relation between ptosis and stasis was hardly so intimate as represented. He had seen one without the other. The changes in the cases of removed colon might be more marked because they were end cases. The only cases that could be susceptible of mechanical explanations were those caused by such gross conditions as tumor or tubercle.

Dr. Jordan supported by skiagrams Lane's views, as also did Dr. A. E. Barclay. The last named remarked that the true intepretation of various discoveries in medicine was best reached by someone standing apart; it was too much to expect it from a worker in the special department.

At the dermatological section of this society some interesting cases were exhibited on the 21st ult. One, very important, of exfoliative dermatitis produced by a single injection of novarsenobenzol. It came on a few days after injection and the patient could not leave the hospital for six months. A member related nine similar mishaps, of which two ended fatally.

Major A. H. Buck, R.A.M.C., made intestinal obstruction the subject of his presidential address at the opening of the session at the Brighton Medico-Chirurgical Society, dealing particularly with cases which came under his personal notice. He expressed belief that inflammatory obstruction might act in one of three ways—by reflex or direct action on nerves governing peristalsis, or by the mechanical action of adhesions. In obstruction, if present, flatus may appear to pass on giving an enema, on account of some air having been injected. Captain Fletcher, R.A.M.C., thought postoperative vomiting, if it continued for ten hours or more, was probably due to obstruction—a history of previous attacks of inflammation was suggestive. Captain Parry said the classical sausage-shaped tumor was not felt in a number of cases of intussusception; the most important signs of it were passage of mucus and blood only; in ileocolitis there was fecal matter also.

A DISCLAIMER.

To the Editor of the Medical Record:

Sir:—A pharmaceutical manufacturing company recently published a brochure upon one of its products in which it says: "Stow in reporting upon his use of the Bulgarian bacillus in children writes: 'There is no class of cases where more brilliant success has been accomplished than in these severe cases of summer diarrhea of infants. The Bulgarian bacillus when rightly employed works with remarkable rapidity and certainty, etc.' 'Metchnikoff's Basic Principle,' etc., by Bond Stow, M.D., Medical Record, August 8, 1914."

I wish to disclaim any association with or recommendation of the product in question, and the use of my name in the advertising brochure is unwarranted and without my sanction. I have never employed the product in my practice nor advised others to do so. I have said that the Bulgarian bacillus when rightly employed, works with remarkable rapidity and certainty. That means a pure, fresh, viable, high bacterial count (1,000,000,000 baccilli per c.c.) culture of this bacillus grown in a medium particularly adapted to the conditions of the gastro-intestinal tract of young suckling infants. The *Bacillus bulgaricus* combined with other substances, particularly those that coat it with an indigestible material, cannot meet these conditions. Both it and the sugars and carbohydrates in the intestinal tract must be free of any impervious nonmetabolizable coatings if the proper action of this microorganism is to be obtained. These two factors must have the readiest access to each other for the prompt generation of the sought-for nascent lactic acid.

6. A Study of the Statistics of the New York State Hospitals for 1913, with Special Regard to Statistics Regarding Dementia Precox. Charles T. LaMoure.

1. Legislation for the Insane in Massachusetts.—Frankwood E. Williams reviews the history of legislation for the insane in Massachusetts since 1907, when the first law providing for the care of insane persons was passed. He states that Massachusetts has today six laws for the temporary care of insane persons, and that of these six laws, four provide care without court action. It is in this that their great significance lies. This freer access to the hospitals seems like a new development. As a matter of fact it is but getting back to the fundamental conceptions of one hundred years ago. In the beginning patients could receive treatment without application to the courts. This continued for many years, but a growing prejudice and misunderstanding, due to the false hopes created in the minds of people by superintendents who honestly entertained these hopes themselves; to the distrust which arose because friends did not sufficiently understand the object in isolating patients; to the fear that developed that patients were being improperly confined resulted in the regulations pertaining to admission of patients to the hospitals being made more and more rigorous, until the time came when there was an almost insurmountable legal barrier about the hospitals. A medical matter became a legal matter. A judge who would hesitate to diagnose a case of heart disease showed no hesitancy in making a diagnosis of mental disease. Happily this stage was now being passed. A study of the present temporary and voluntary care laws shows that they are valuable for the following reasons: 1. They tend to express in legal form the modern conceptions of mental disease; and without endangering the personal liberty of any individual. 2. They at the same time emphasize the patient's cause as a patient. 3. They make it possible to provide early treatment, which is the most hopeful treatment. 4. They afford protection to the patient both from himself and from unprincipled members of the community quick to take advantage of his illness. 5. They afford protection to the family and community against the

acts of a patient. 6. They obviate in a large number of cases the delays, legal exactions, semi-publicity, and stigma of having been declared insane. 7. They remove the hospitals from the isolation they have suffered in the community and make it possible for them to take their place as hospitals in fact as well as in name, a more integral part of the social fabric. 8. They make possible a wider cooperation between the hospitals and the lay and medical public, which will yield to the Commonwealth which supports them a greater usefulness. 9. And, finallly, by means of a wider understanding of the more fundamental facts in regard to mental disease on the part of physicians, cooperating with the hospitals, through the more frequent use of these laws it may be possible to prevent certain forms of mental disease.

2. **Report of Harvard University Service at the American Ambulance, Lycée Pasteur, Neuilly-sur-Seine, France.**—Robert B. Greenough states that this service was generally known as the Harvard Unit and took charge of the University Service of the American Ambulance from April 1st to July 1, 1915. This service was composed of eighteen wards, containing ten or eleven beds. All the administrative departments of a modern hospital had been established and one could not reasonably ask for more favorable conditions under which to work. A system of triplicate records with a card index was put into operation on April 10. These records show that 441 cases came under the charge of Harvard University service and of these they have records of 383. Of these 441 cases, seven died. Thirty-nine of the 383 cases were miscellaneous diseases and injuries without wounds. Of 154 wounds by bullets, 128 were perforating wounds and in 26, or 16.8 per cent., the bullet lodged. Of 32 wounds produced by shrapnel balls, 17 were perforating and in 15, or 46.8 per cent., the missile lodged. Of 161 wounds produced by shell fragments, 89 were perforating and in 72, or 44.7 per cent., the fragments lodged. Many of these cases presented more than one wound, and in many more several different anatomical structures were affected. The different lesions were classified and studied, giving data on some 670 instances of special medical or surgical conditions. The writer analyzes these groups of cases and states that a more extended report on the surgical aspects of the work is in preparation.

3. **Artificial Pneumothorax.**—Edward O. Otis refers to the vast amount of literature on this subject and states that from the extensive evidence at hand from all over the world no one can now deny the value of artificial pneumothorax in pulmonary tuberculosis when other means fail. In some cases it brings about an arrest of the disease not otherwise attainable; in other cases, a relief from one or more distressing symptoms. However, in the author's opinion, its applicability is limited, it is often unsuccessful, and should only be undertaken after careful consideration of each individual case. There seems to be little doubt that the unilateral cases with but little or no infiltration in the other lung, that are inactive, and in which there is still a fair amount of resistance, offer the most favorable conditions for this treatment and give the best results. To assume that if the operation does no good it will do no harm, is, in the author's opinion, false; for there is always the possibility of pleural shock, gas embolism, subcutaneous emphysema, infection of the pleural cavity, disturbance of the blood supply from displacement of the heart, and a lighting up of the inactive process in the other lung. One must also bear in mind that although the surgeon considers the operation a very simple one, to the patient it means an operation with all the dread that the word suggests. The consensus of opinion is that one is not justified in carrying out this treatment without constant access to the *x*-ray with a skilled technician. The scope of artificial pneumothorax is apparently not yet determined, but it has fully justified its place in the treatment of some severe cases of pulmonary tuberculosis; however, it does not take the place of well-known measures for increasing and maintaining the resistance of the patient.

4. **On the State of the Respiratory Mechanism in Pneumonia.**—J. H. Means, L. H. Newburgh, and W. T. Porter describe their experiments on cats to determine the percentage increase in tidal air due to the progressive increase in the carbon dioxide breathed. It is known that when an animal breathes through a closed system of tubes, the amount of the carbon dioxide in the inspired air progressively increases. In normal animals, the volume of the tidal air, *i.e.* the volume of the air passing in and out of the chest, increases with the increase in carbon dioxide until the reaction ceases. In our observations, the reaction of normal animals continued usually until the volume of the tidal air was four or five times greater than when the animal breathed only atmospheric air; in our highest observation, the increase was seven-fold, at which point the animal was still reacting. The increase of carbon dioxide in the inspired air is, therefore, a stimulus to the respiratory mechanism, and the state of that mechanism may be measured by determining the ratio of the tidal air (cubic centimeters per minute) to the percentage of carbon dioxide inspired. As a result of these observatons they conclude: (1) that the reaction of the respiratory mechanism to carbon dioxide is greatly diminished in pneumonia, and (2) that the graver the disease the less is the reaction.

5. **Exercise in the Treatment of Severe Diabetes.**—Frederick M. Allen says that the fact that muscular exercise is a useful means of increasing tolerance in cases of mild or moderate diabetes led them to make tests on diabetic dogs with a known tolerance for carbohydrate or protein. It was found that vigorous exercise on the treadmill raised the tolerance of such animals as judged by the sugar in both urine and blood. In some experiments dogs which for months past had regularly shown glycosuria whenever they were given 100 grams of bread, on exercise became able to take 200 grams as a regular daily ration without glycosuria. Tests with patients are more recent, but the results thus far appear sufficiently favorable to warrant recommending exercise as an addition to the treatment. With due precautions against nervousness and sleeplessness due to over-weariness patients are worked right up to the limit of their strength like athletes in training.

6. **Statistics of New York State Hospitals for 1913, with Special Reference to Dementia Precox.**—Charles T. LaMoure finds that during the year 1913, 8269 patients were admitted, and 7294 were discharged. Of the number admitted there were 1,021 cases of dementia precox first admissions of practically one-eighth of all admissions. Of these the following were the type of cases: Paranoid 542; katatonic 66; hebephrenic 299; simple 98, and unspecified 16. The greatest number admitted were between twenty and twenty-four years of age. There was no history of insanity found in 537 of these cases and no history of alcoholism in 598. There was no history of any nervous disease in 408 cases. During the year 548 cases of dementia precox died, the greatest number being between the ages of

35 and 39 years. As only 16 cases of dementia precox were discharged as cured during this year, and only 259 cases as improved, it seems that methods of treating this form of mental disease are lacking.

1. Peritonitis.—John B. Deaver and Damon B. Pfeiffer emphasize the importance of keeping always in mind that peritonitis is not so much a disease in itself as it is a complication of diseases, and that it varies most remarkably in its character and course. After considering the pathology of the condition, they state that prognosis is influenced by the type and degree of the infection, the situation of the infection, the time of operation, the operation itself, the pre-operative and the post-operative treatment. In discussing the time for operation, they state that it is impossible to lay down a general rule, but that it may be said that it is seldom possible to act too quickly in peritonitis caused by the appendix, or a perforated gastric or duodenal ulcer, while in peritonitis of pelvic origin, delay should be the rule. Peritonitis of rapid spreading character seldom comes from the gall bladder. When present it is usually due to perforation and demands quick action. Another important rule in the presence of acute peritonitis is to do the least consistent with the ends of operation and in the shortest time compatible with good work. There is one exception to this, namely, the performance of a gastroenterostomy at the same time as the closure of a perforated gastric or duodenal ulcer. The authors say that their plan in perforation is to close the perforation, do a gastroenterostomy, and establish pelvic drainage through a suprapubic stab. Never do they irrigate. As for a spreading peritonitis not yet general the physiological treatment is better than the operative. There is no surgical treatment for general peritonitis. All the victims die with the exception of a few that prove the rule. Similarly for acute spreading peritonitis it is fallacious to hope that incision and drainage will limit its advances. On the other hand the indications are to put the intestinal tract at rest by withholding everything by mouth, by placing the patient in the sitting posture to favor gravitation of the inactive fluids to the pelvis, and by giving him constant enteroclysis. When the outlying inflammation subsides and centers about the appendix it is time to operate upon the patient. With reference to the post-operative treatment their slogan is "let him get well." If the operation has been properly timed and well executed, there will be little to do and the less done the better, though a sharp watch must be kept for complications.

3. Cancer Treated with Autolysin.—Henry Smith Williams presents a summary on the autolysin treatment of cancer that represents the findings not alone of Dr. Beebe, but of sixty other regularly qualified practitioners who have had personal experience with autolysin in inoperable cases of cancer. There are also more than 300 other physicians of corresponding standing in various parts of the country who have tested autolysin on at least one patient, tentative reports from a large number of whom are available. All told 1,000 inoperable cases of cancer have been treated with autolysin. About 600 cases have been treated long enough to get somewhat definite results, the remaining 400 have been treated for too short a period to furnish material for a statistical summary. The writer finds that setting aside the small number of cases that were in such a desperate condition that no expectation was entertained that anything could be done for them, it may be said that a more or less specific action has been observed as a practically uniform sequel of the administration of autolysin, there was a marked alleviation of unfavorable symptoms, and in a good many of these cases life was somewhat prolonged. In fact, seemingly about 64.6 per cent. of the whole number have to some extent been benefited by the autolysin treatment.

5. Anesthesia by the Rectum in Thyroidectomy.—Walter Lathrop has used a slight modification of Dr. James T. Gwathmey's oil-ether, colonic anesthesia in 111 cases of goiter and is convinced that in it he has an ideal method superior to inhalation. He summarizes as follows: 1. It is most valuable in head and neck operations. 2. There is no fear, as is so often seen in the usual method. 3. The pulse and respiration, as a rule, remain near normal, or do not vary much from their conditon when the operation is begun. If rapid, as in hyperthyroidism, it remains rapid, but does not increase as when fear is added to the troubles of the patient. 4. There is less tax on the lungs and kidneys. 5. Operations can be done without the knowledge of the patient, which is surely valuable and must play some part in anociassociation, while Crile's technique may be carried out, if desired.

9. Trachoma and Follicular Conjunctivitis.—M. B. Beals says that the usual routine treatment of trachoma and follicular conjunctivitis by blue stone, tannic glyceride, argyrol, etc., has shown but poor results when applied in the thousands of school children on the records of the Health Department of New York. The writer finds that the intense bichloride rub, combined with the treatment indicated to modify the intense reaction whch often follows the first few applications is so far superior to the other methods that it should supersede them in nearly all cases. One of the most pleasing features of this treatment is that no scar tissue results.

1. Elective Localization of Streptococci.—Edward C. Rosenow records a summary of the results obtained from the intravenous injection, under a standard technique of streptococci isolated from appendicitis, ulcer of the stomach and duodenum, cholecystitis, rheumatic fever, erythema nodosum, herpes zoster, epidemic parotitis, myositis and endocarditis, and discusses the bearing of these results on the localization of streptococci.

A study of a table showing the elective localization of streptococci shows that streptococci from the various diseases often have a striking affinity or tropism for the organ or tissues from which they are isolated. Thus, fourteen strains from appendicitis produced lesions in the appendix in 68 per cent. of the sixty-eight rabbits injected, which is in marked contrast to an average of only 5 per cent. (given in lowest line of table) of lesions in the appendix in the animals injected with the strains as isolated from sources other than appendicitis. Eighteen strains from ulcer of the stomach or duodenum produced hemorrhages in 60 per cent. and ulcer of the stomach or duodenum in 60 per cent., a combined total of 74 per cent. of the 103 animals injected, in contrast to an average of 20 per cent. hemorrhages and 9 per cent. ulcer following injection of other strains. Twelve strains from cholecystitis produced lesions in the gall bladder in 80 per cent. of the forty-one animals injected, in contrast to an average incidence of lesions here of only 11 per cent. with the other strains. Twenty-four strains from rheumatic fever produced arthritis in 66 per cent., endocarditis in 46 per cent., pericarditis in 27 per cent., and myocarditis in 44 per cent. of the seventy-one animals injected, in contrast to an average of arthritis in 27 per cent., endocardial lesions in 14 per cent., pericarditis in 2 per cent. and myocarditis in 10 per cent. of the animals injected with strains from sources other than rheumatic fever. Six strains from erythema nodousm produced lesions of the skin in 90 per cent. of twenty animals injected, in contrast to an average of 2 per cent. in the animals injected with the strains from sources other than erythema nodosum and herpes zoster. Eleven strains from herpes zoster produced herpetiform lesions of the skin, lips, tongue or conjunctivæ in 77 per cent. of the sixty-one animals injected, in contrast to the average of only 1 per cent. of what seemed to be herpes of the skin with the other strains. Nine strains of streptococcal organism from epidemic parotitis produced lesions in one or both parotid glands in 73 per cent. of the nineteen animals injected intravenously, in contrast to no instance of lesions here with the other strains. Three strains from cases of true myositis produced myositis in 75 per cent. and myocarditis (chiefly of the right ventricle) in 35 per cent. of the forty animals injected, in contrast to an average of myositis of 12 per cent. and myocarditis of 10 per cent. following injection of strains from sources other than myositis or rheumatic fever; and eight strains of *Streptococcus viridans* from chronic septic endocarditis produced lesions in the endocardium in 84 per cent. of the forty-four animals injected, in contrast to an average of 15 per cent. with the strains other than those from endocarditis. The results detailed in this and in previous papers seem to bring the necessary experimental proof that chronic foci of infection play a most important role in causing systemic disease, a fact which has been observed and frequently commented on by different observers, but has been recognized in its full clinical significance by Billings.

2. **Influence of Peptone on Tolerance of the Body for Homogenous Ovarian Transplants.**—Louis A. Mitchell thought that it might be profitable to undertake certain animal experiments in order to determine whether or not the repeated periodic injections of a solution of Witte's peptone would increase the tolerance of the body to grafts of foreign tissue and reaches the following conclusions: Peptone injections tend to intensify rather than inhibit the reaction of the host against homogenous grafts of ovarian tissue; such injections of peptone produce a condition of reduced metabolism in the animal, but not to such an extent as to prove dangerous to life; an abundant blood supply to the graft does not indicate that it is viable in its new environment, but rather may be evidence of an intense reaction against it on the part of the host; the destruction of the graft is practically complete by the sixth week, both in animals injected with peptone and in those not injected; the host primarily reacts to the presence of the graft by revascularization of its tissues, and the further reaction which evidently involves the destruction of the graft is evidenced by round-cell infiltration and proliferation of the connective tissue of the host; the presence of peritonitis within a few days destroys the viability of intraperitoneal grafts.

3. **Detachment of the Retina with a Preliminary Report of a New Operative Procedure.**—Edgar S. Thomson and Thomas H. Curtin believe they are justified in the two following assumptions: First, the presence of the detachment in itself leads to lymphatic disturbances and further complications of a degenerative nature; second, the evidence on all sides is in favor of some operative procedure which withdraws the subretinal and subchoroidal fluid. In the past when simple sclerotomy has been done and the fluid evacuated, it has been the rule to find a marked improvement in an attempt at reattachment. They have endeavored to secure permanent drainage by means of a trephine opening in the sclera, through which the subretinal fluid can be completely removed by aspiration with a small syringe. It is evident that the procedure outlined, in order to be successful must be undertaken before the detachment is old enough to have undergone degenerative changes. The rationale of the operation is in recent traumatic or spontaneous detachments where there seems a likelihood that the fluid accumulation is acting to keep up the condition.

4. **Sclerotrephine Operation for Detached Retina with a Clinical Report of Eleven Cases.** — Walter R. Parker reports an operative procedure the object of which had been to secure an opening in the sclera and choroid which will allow free drainage of the subretinal fluid for a sufficient length of time to permit the retina to become reattached. The procedure seems to be unattended by any danger, and the results obtained, as compared with those from any like number of cases previously treated, compel the author to look on the operation as one of distinct value in the treatment of detachment of the retina.

7. **A Study of Immunity Following the Use of Typhoid Vaccines and Serobacterins.** — W. E. Richard Schottstaedt says that in order to gain more information regarding the immunizing value of the various sensitized and non-sensitized typhoid vaccines in use at the present time, a series of experiments on rabbits was undertaken. Following the inoculation with such vaccines, blood was withdrawn at regular intervals, and estimations of the opsonic index and the agglutinating and bactericidal powers were made. He finds that there is a slight reaction following the injection of non-sensitized vaccines in rabbits, which is absent following the injection of sensitized vaccines. Vaccines killed by heat seem to be less active than those killed by the addition of phenol only. Washing the vaccines does not seem especially to influence their immunizing value. The height of the immunity curves occurs earlier after sensitized than non-sensitized vaccines, but the former appear to be only about one-fourth as potent. The agglutinins disappear within three months after the first injection, while bactericidins and opsonins can be detected much longer. Opsonins increase more quickly than do agglutinins and bactericidins. Opsonins and bactericidins remain more permanent than agglutinins, and immunity is more

likely due to the former than to agglutinins. Sensitized typhoid vaccines are less potent than non-sensitized typhoid vaccines, probably because the bacteria of sensitized vaccines undergo phagocytosis and bacteriolysis more rapidly. In conclusion he states that in conditions in which a prolonged reaction is desired, as in conferring immunity, the non-sensitized vaccines seem preferable. In conditions in which no general reaction is wanted and a quick response of the protective powers is desired, as in active typhoid fever, a sensitized vaccine would seem preferable.

10. Nephritis. — W. Ophuls reports a new series of cases with a review of recent literature and gives a brief summary of his findings as follows.: 1. Nephritis from an anatomic point of view may be best subdivided into: (a) acute, subacute and chronic *parenchymatous nephritis* which is very frequently associated with amyloid; (b) acute, subacute and chronic *glomerulonephritis* to which class belong most of the cases with continued definite urinary findings, renal hypertension, uremia, and other definite symptoms of renal disease. 2. Hypertonic cardiovascular disease may involve the kidneys more or less extensively, often causes certain functional disturbances in the kidneys, may cause contracted kidney, but should be segregated entirely from true nephritis. 3. The cause of true nephritis is continued bacterial septicemia, and the lesions in the kidneys are probably due to rapid bacteriolysis and incidental liberation of large doses of toxic material in and about the affected glomeruli. 4. The lesions in the arterioles, in at least some of the more chronic cases, are due to the organization of a hyaline (thrombotic?) deposit on the inner surface of the arteries which at times is found underneath the endothelium.

2. The Harveian Oration.—Sidney Coupland delivered this oration at the Royal College of Physicians of London on October 18, 1915, in which he first refers to the war and the special tragedy that it has brought to them as scientists. He then reviews the life and work of Harvey and shows that the impetus given by the discovery of the circulation of the blood to the study of animal functions was not confined to the solution of physical problems, but that it had also proved to be the starting point of attempts to explain the relationship between mind and body. He finds that the philosophy of Descartes and of Hobbes was influenced by the light shed by Harvey's discovery. He goes on to show that while psychology has traveled far from the standpoints of either Descartes or Hobbes, the great problem of the real relation between mind and body remains unsolved. And although we must be content to remain ignorant of the real nature of mind there is an enormous and still untraversed area for research into the causation and characters of insanities. He sketches the progress that has been made, and is still being made, in the treatment and the study of insanity and expresses the hope that we may see the day when, in respect to scientific work, the asylums for the insane in various localities may become affiliated to universities in their vicinity, so that workers in such centers may be enabled to draw from many sources the material needed for research, which might then be conducted on definitely coordinated lines. He discusses the two great divisions of insanity, based on the work of Dr. Shaw Bolton, amentia and dementia; the relation of alcohol and syphilis to insanity, and the hope that psychoanalysis holds out. Of the latter he says that while it has been encumbered with theories and speculations which are not only difficult to accept, but in some respects positively repugnant, the central hypothesis affords a reasonable basis for the explanation of many of the most characteristic symptoms of mental disorder, and that working on this hypothesis it is possible to pluck from the memory a rooted sorrow or eradicate a long-held delusion, and thus restore mental balance. The writer believes that while there is recognition of the advantages to be derived from skilled advice and care in the earliest stages of insanity, yet this advantage can often be secured only with the greatest difficulty and often not at all. This is largely due to the deep rooted misconception of the nature of mental disease, a persistence in the public mind of medieval ideas of possession and the like, giving rise to an aversion, consciously or unconsciously felt, for anything associated with lunacy. For this the law is not to blame; it is for the scientists and the physician to remove from the path of science and humanity the last cumbering relic of the Middle Ages.

3. Case of Tetanus of Short Incubation Period.—R. Lester Scott relates the history of a lieutenant, admitted to a base hospital, suffering from a circular punched out wound on the anterior aspect of the left thigh, about the middle third, which had been received two days previously. The wound discharged pus and liberated gas on pressure. It was operated on the day following admission. Two days later the patient complained of pain in the wound and jerking in the affected limb. Within a few hours well developed symptoms of tetanus developed. Serum was administered both intravenously and intrathecally, 102,000 units in all being given. The interesting features of the case are as follows: 1. The incubation period was short. 2. There is no doubt that the operative interference some days after wound infection had a definite effect on both the onset and the severity of the attack. 3. There is equally no doubt that the attack was a severe one, characterized by clonic and tonic seizures associated with great pain. 4. The essence of the treatment consisted in the adoption of immediate, persistent, and almost extravagant serum therapy. 5. The result of the treatment was an uncomplicated recovery, with entire absence of secondary lesions.

4. Congenital Pulmonary Stenosis.—Douglas Martin states that it may appear to some to be incredible that pulmonary stenosis can be present in children without producing obvious symptoms. Yet in the school inspection of 5,000 or 6,000 children annually, though there are many affections discovered only then, none are so striking to the writer as the cases of congenital pulmonary stenosis. He cites five cases brought in this way for the first time to the attention of the parents. The height, weight, nutritional and mental condition of the children was outwardly unimpaired, and the children showed none of the usually obvious signs of pulmonary stenosis. The writer believes that these cases serve as an illustration of the utility of the medical inspection of school children for the detection of unrecognized conditions requiring treatment and care. In the examination of children he recommends the method of auscultation at the pulmonary area first.

5. Hypertonic Saline Solution in Gynecology.—Clifford White states that the use of hypertonic saline solution is being attended with such success in the treatment of septic shell wounds that it may not be out of place to draw attention to the value of such

solutions in the treatment of surgical affections of the female pelvis. He has been using a solution made of four drachms of sodium chloride and one-half drachm of sodium citrate to each pint of water as a vaginal douche in all inflammatory and septic cases in which a douche is required and finds that the effect is better than that of the antiseptic douches previously employed. In puerperal cases with sloughing of the perineum and vagina the effect is extraordinary. In gynecology all forms of infected and congested pelvis respond well, such as salpingitis, cellulitis, gonorrhea, vaginitis, and erosions of the cervix. Among the most striking results is the way in which a carcinomatous cervix cleans up before operation. In cases in which drainage per abdomen is necessary on account of acute infection the results of saline irrigation of the drainage track have been highly satisfactory.

3. The Recruit's Heart. — Alexander Morison, who during the progress of the present war has had to consider, both in hospital and private practice, the suitability of officers and men for military service on account of some cardiac condition or anomaly, comments on Sir James Mackenzie's memorandum on the recruit's heart, believing that this memorandum requires both amplification and modification. He states in general terms that the heart which manifests an endocardial bruit after the exertion of coming to the recruiting office and having been given exercise there to determine its persistence, is either organically affected, or, if "functionally," shows such a degree of lack of tone in the cardiac muscle that the recruit should only be accepted on probation. It seemed from the memorandum referred to that the writer would not hesitate to accept one who showed organic valvular lesion provided the muscular action of the heart satisfied him. Experience, however, has satisfied the Army Medical Service that there is wisdom in absolutely rejecting the recruit with organic valvular disease of the heart. What is true of the heart affected with functional endocardial murmurs is true also of the extrasystolic heart and of auricular fibrillation, which at the recruiting age is usually found associated with mitral valvular disease. The negligible functional bruit at the apex of the heart which should disappear on assuming the erect position and rhythmical variation of pulsation associated with respiration, coupled with an occasional reduplication of the second sound, being purely physiological is no cause for rejection.

4. Effect of Exertion on the Circulation.—J. M. Macphail says that in making the tests as the results of exertion on the circulation sphygmographic observations have held a prominent place, but doubt has been thrown on their value as an index to the work performed by the heart or a guide to its functional ability and a method is surely defective which merely registers the maximal pressure but fails to indicate the pressure maintained between the arterial beats. The author in making his observations has used the sphygmograph of the Mackenzie clinical polygraph and has followed the following method: A tracing of the pulse was taken in the sitting and the erect posture, and with the sphygmograph and paper still in position, the patient was asked to ascend twenty steps. Immediately on arriving the clock work was again set in motion and the result was a study of the pulse within the first second or so of the completion of the exertion. As the pulse changes in character so rapidly from moment to moment time is all important in recording the delicate changes. The author gives the tracings with their explanations in six cases and concludes as follows: 1. Exertion causes a rise in systolic pulse pressure, though a general vasodilatation may nullify this effect. 2. There is always a lowering of diastolic pressure. 3. In heart disease with failing compensation the fall in diastolic pressure is most pronounced, and there is often an almost complete absence of the predicrotic wave pointing to a diminished systolic pulse pressure.

5. Rapidity of the Pulse. — Knowles Boney reports his observations on twenty cases of rapid pulse, the subjects being all Indians from the Indian Expeditionary Force in Flanders, who after various injuries and ailments had been transferred to a convalescent camp. When first seen by the author these men all presented the same general characters—a tired, listless expression, fatigue on walking a few yards, and in two instances undue shortness of breath after such slight exertion. In no case was there any complaint made of pain, palpitation, or other subjective symptoms. After giving a more detailed history of these patients, the writer states that everything points to a central lesion of the controlling nervous mechanism. The patients neither showed signs of hypertrophy nor of dilatation supervening on hypertrophy. There was nothing in the condition analogous to the staleness of the overtrained athlete, neither was there evidence of complete breakdown due to cardiac overstress from hard work. The somewhat vague expression "irritable heart" has been applied to two states which are radically different, the one a functional condition occurring chiefly in growing boys, and eminently curable; the other comprising the group also known as "soldier's hearts," a condition involving more or less permanent myocardial damage and too often incurable. In these cases there was no evidence of such damage. Furthermore, in the writer's cases there was no history of great muscular effort. The history was one of laborious work of more or less vexatious nature, spread over a considerable time in a strange climate and frequently under conditions of great personal danger. The causation was probably to be found in a great complexity of factors into which the psychology of the Indian, exposure, shock and fatigue in a climate to which he is unaccustomed, all enter.

7. Successful Early Operation in Wound of Small Intestine.—John H. Stephen relates the case of a private who was operated on within a half hour after having received a penetrating wound of the abdomen. And end-to-end intestinal anastomosis was performed with the greatest possible speed and with rather rough and ready materials for an operation of that kind. The patient made a very rapid and excellent recovery. The author believes that this case offers proof that many cases of abdominal injury might be saved if dealt with on the spot by the field ambulances, instead of undergoing operation after a long and exhausting journey and the delay of many hours in a casualty clearing station. He also states that the German military surgeons now incline to the idea of operating early and on nearly all abdominal cases coming into the field hospitals, and that their statistics show that

the mortality in these cases is in direct proportion to the length of time elapsing between the wounding and the operation and to the length of journey that the patient has to undergo before treatment.

Berliner klinische Wochenschrift.

September 27, 1915.

Treatment of Pneumonia with Ethylhydrocuprein.—Lowe and Meyer have treated forty-three military cases of pneumococcus infection with this remedy. The crisis in pneumonia is due to the formation of immune bodies, which so weaken the virulence of the infection that the leucocytes can attack and destroy the pneumococcus. In theory, therefore, pneumonia should be treated with an antiserum and some chemotherapeutic remedy which can stimulate leucocytosis. Of the forty-three cases all but two were pneumonias, the exceptions having been pneumococcus meningitis. Of the pneumonias twenty-eight were primary and single, eight primary and double, while the remainder were associated with measles, pleurisy, and empyema. There were two fatalities, one recurring in an empyema case after operation and the other in the measles case. These patients, naturally vigorous, were much worn with forced marching and other hardships and showed nervous collapse, dilatation of the heart, and other complications. In fact every case treated was severe in type. Aside from the Römer serum and ethylhydrocuprein the patients received digitalis, caffein, camphor, oxygen inhalations, morphia, and large quantities of alcohol. The duration of the fever averaged one week. A crisis almost invariably set in, but passed into a lysis. Most of the credit is awarded to the ethylhydrocuprein, and especially in the meningitis cases. The majority of patients received about 4 grains of the drug from four to six times daily. No disorders of vision were noted. The quantity should perhaps be somewhat higher—six to eight doses daily—and when given at the outset of the disease the authors feel much confidence in its ability to control the disease.

Diagnosis of Farcy.—Pfeiler devotes much space to the diagnosis of farcy in animals and man, but does not appear to arrive at any dependable results such as might guarantee a diagnosis of the chronic disease. It was formerly taught that an inoculation test on the mouse was a certain criterion (orchitis), but this is no longer even mentioned by the serologists. An inoculation test is now practised in the guinea-pig, and it is said to be easy to cultivate the *B. mallei* from the secretions of the inoculation wound. There must, however, be many negative results, for the author never employs it alone. If there are unopened abscesses the author obtains "sterile" pus from them, and in some cases finds the bacillus in ordinary smears. Under such circumstances he does not wait for inoculation results. To the experienced even the histological picture may suggest farcy as it may be quite characteristic at times (pyknosis, presence of neutrophile leucocytes to the exclusion of others). Serological tests, apparently, must seldom be omitted because they may give very prompt results. These consist of trial agglutination and complement deviation tests. To increase the likelihood of a positive result in the latter polyvalent sera are recommended.

October 4, 1915.

Treatment of Congenital Syphilis.—Müller, in connection with a home for orphans and other institutions has under treatment from fifty to sixty children at a time throughout the year. Treatment has become modified in consequence of the new medicaments and viewpoints. Judged by the Wassermann reaction the older plans of treatment must have been insufficient. He gives even to nurslings intramuscular injections of calomel suspended in olive oil and of neosalvarsan in alternation. During the first year the infant receives several cures with intermissions. This intensive treatment is given not because of any severity of symptoms but with the aim of eradicating the disease before the child shall have passed from control. In the second year of life mercurial inunctions are given in addition to the two kinds of injection. A negative Wassermann reaction does not mean a permanent cure and so-called prophylactic cures are continued until the possibility of relapse seems excluded. The author sees both comparatively rapid and delayed results under a common plan of treatment.

Influence of Muscle Work on Blood Sugar.—Von Moraczewski seeks to learn whether exercise tends to produce glycemia. This form if it exists may be compared with alimentary glycemia, although the two conditions are quite distinct. The alimentary type probably depends on defective synthesis of glycogen, the movement type on delayed absorption of sugar from the muscles or elsewhere. Experiments on a diabetic showed that exercise always tends to cause a rise, and rest a fall in the glycemia. The author also fed cane sugar freely to men after hard labor, but found no trace of sugar in the urine nor was the percentage in the blood materially varied. In other words exercise increases carbohydrate tolerance in the healthy. The diabetic's glycosuria disappears during a febrile period, and while resting he burns up less sugar than while active. A sort of parallelism is seen in this respect between sugar in the blood and uric acid in the urine—increase of both being due to the same failure in combustion. Even with subjects profusely sweating, with scanty urine, the elimination of uric acid is unchanged.

Treatment of Cancer of the Buccal Cavity, with Radium.—Sticker writes at great length of fifteen cases of cancer favorably influenced by radium treatment. Since mutilating operations in this region cause such hardships, radium alone can hold out some hope of escaping the latter. Such cases are too often inoperable, especially when recurrent. Radium treatment is intended for two purposes—one to secure an anatomical, *i.e.* nonmutilating recovery while the other is to attack early relapses *in situ*. The danger of implantation recurrence is also done away with. The author first reports three cases of cancer of the tongue which he sums up as follows: a large, crateriform ulcer was made to heal like any simple ulcer; a leukoplakia area in cancerous degeneration was restored to its original condition and a cancerous nodule in the center of the tongue was made to disappear. Results of the same character were obtained in seven cancers of the upper and five of the lower jaw and two of the cheek. These results were evidently due in great measure to the technique. The radiation took place at night and was maintained too many hours on fourteen consecutive nights. Much ingenuity was evidently required to adapt the tubes to the area to be rayed and to render them endurable. The *x*-ray photographs helped to show when the tubes were properly inserted. The aid of a dentist was invoked for the prepartion of special tube holders. These cases may recur but the author has relieved all pain and functional disability without any loss of tissue.

Münchener medizinische Wochenschrift.

October 5, 1915.

Boeck's Sarcoid with Participation of Internal Organs.—Kuznitzky and Bittorf collaborate on this subject, respectively as dermatologist and internist. The former reports the case as a peculiar dermatosis in which a

diagnosis was at first impossible. Firm, brownish-red, non-pruriginous, slightly desquamative papules with indolent enlarged inguinal lymph nodes, although suggesting lues, were rather interpreted as plexiform neurofibroma, the Wassermann reaction having proved negative. The microscope when called upon, at once made the diagnosis of Boeck's sarcoid. In addition to the papules already mentioned which were diversified over the lower extremities, lower part of the trunk and upper extremities were accompanied by subcutaneous nodules. Boeck's opinion was that his sarcoid belonged to the group of infectious granulomata which would not exclude the likelihood of internal manifestations. In the interest of simplicity efforts must in such cases be made to exclude the known forms of granuloma, especially tuberculosis and lymphoid forms. Thus far other than superficial manifestations have been bronchitis, iritis, enlarged spleen, and other indefinite symptoms. The author's patient reacted negatively to several tuberculin tests. Professor Bittorf now took up the examination, and found a personal history of maladies attacking at different times the thoracic organs, stomach and kidneys. The patient, a man of 27, who had been fit at one time for military service, had become greatly emaciated and weak. The chief seat of mischief seemed to be the entire right lung which was the seat of râles, bronchial sounds and other indications of disease. There was but little sputum, no fever, no tubercle bacilli. Evidences of chronic nephritis were present. The slightest exertion caused dyspnea and a little cyanosis. The blood picture was not much affected. Arsenic provoked an intercostal zoster. The lungs, which at first gave a mottled shadow, improved under treatment. The patient also improved to such an extent that he was discharged. These manifold and varying evidences of implication of viscera with no serious outcome could mean but one thing—they were made irritable by deposits within their substance akin to those to be seen on the surface. The history also pointed to a succession of such deposits even before the appearance of the skin lesions. The nearest congener of such an infection is Hodgkin's disease. The links here seem to have been the enlarged lymph nodes and spleen, the blood count and unfavorable symptoms due to arsenic.

Uses of Old Newspapers in the Army. — Weisbach mentions the use of newspapers for inner soles and for wrapping the feet; for packing the joints in mild rheumatic disorders, and especially for the shoulders and elbows. They may be worn outside the shirt without any hindrance to motion. By superimposing a number of sheets good back and side warmers may be extemporized. Newspapers may also be made to serve as moist dressings, poultices, etc. In the barracks newspapers can be used for filling sacs and if first finely divided by machinery may be packed evenly. Perhaps as a result of the printer's ink insects are kept at a distance from barracks in which newspaper has replaced wool, etc. Even housewives know that newspapers can be used with success against moths.

Deutsche medizinische Wochenschrift.

September 30, 1915.

Abortive Forms of Cerebrospinal Meningitis.—Hochhaus states that these may be so slight or transitory as to be readily overlooked. Often, in fact, the medical man was not consulted. However, in garrison practice these forms do not escape detection, in fact there is a constant watch kept for them. Literature is comparatively silent as to abortive forms. During the present year 32 cases of cerebrospinal meningitis were announced. Of this number 13 were in soldiers and 8 of them came under the author's care while 16 suspects also came before him. The latter had been exposed to the contagion and had further developed certain suspicious symptoms. These had come on suddenly, without prodromes, and comprised headache, soreness of the neck, rigors, and vomiting. Other symptoms more or less common in meningitis were less constantly in evidence. In some of the cases, but one or two days advanced when first seen, the symptoms had already relaxed in severity, while in others the typical picture of the disease was present to the full. In all the patients there was a simple angina and the majority had also bronchitis. Smears from the nasal mucus showed the meningococcus only in a minority of cases. The results of lumbar puncture were even less satisfactory in this respect. These defective finds, however, may accompany fully developed epidemic cases. The author gives 5 histories of aborted disease, and in summing up claims that in all probability these could have been nothing else than meningitis, even if for some of them strict proof was not forthcoming.

Etiology of Gas Phlegmon.—Selter investigated fourteen cases of this lesion microscopically and culturally. In four of these the presence of spores could not be demonstrated at any time; while in the others they could never be found in the open wound although invariably present in the muscles. At first the author believed that he had to do with Fraenkel's bacillus throughout but these spore-containing bacilli were certainly different in the series of ten cases from Fraenkel's germ which was doubtless responsible for the series of four cases. The unknown spore-containing bacillus bore a similarity to the anthrax bacillus, and authors have described a denatured form of the latter, which in turn strongly resembles the bacillus of butyric acid. This bacillus has lost the locomotive properties present in *B. anthracis*, as well as its sporing capacity. Fraenkel himself has seen gas gangrene which resembled clinically malignant edema. The author has had no opportunities for cultural comparisons as for inoculation experiments. Clinically every one of his fourteen cases corresponded to the typical form of gas gangrene as described by Fraenkel and not to the atypical forms. His thesis therefore is simply that different forms of microorganisms can cause a common clinical type of gas phlegmon. The various bacteria preexist in the soil as anaerobes. Hence the prospect of producing an antiserum for gas phlegmon is rather dubious. The author has found bacilli like Fraenkel's in simple wounds and this suggests that all fresh wounds contaminated by the soil should be treated at once as potential gas gangrene.

Pituitrin's Effect on Lactation.—Maxwell and Rothera experimented by injecting "pituitrin" into cows and goats and noting its effect on the secretion of milk. They found that it causes a temporary secretion of an extra amount of milk.—*Journal of Physiology.*

Use of Tobacco and Snuff by Children. — Professor Stiles of the U. S. Public Health Service has made a study of the use of tobacco by white school children in the city of X where he finds less than 1 per cent. of the 2,215 white school children admit chewing tobacco and less than 1 per cent. admit dipping snuff, while 3.25 per cent. admit smoking. In all 4.2 per cent. admit the use of tobacco (chewing or smoking) or of snuff. Smoking and chewing were admitted only by boys, while more girls than boys admitted dipping snuff. The use of tobacco was found to be more common among children from homes with inferior sanitation (privies) than among those from homes with better sanitation (sewer connection).—*Public Health Reports.*

Insurance Medicine.

The Medical Referee.—A paper with this title was read before the Medical Section of the American Life Convention by Dr. Daniel W. Layman, medical referee, New York Mutual Life Insurance Company. He said that the medical referee system of the Mutual Life Insurance Company of New York had its beginning in the year 1908. The first year or two the system was on probation. It was first tried out at the company's general agencies in the large cities and met with such approval that it was gradually extended to other agencies, after due consideration and careful and deliberate investigation of the system.

The duties of the medical referee may be classified as follows: (1) Revision of all examinations, certificates of health, and special reports. (2) Action on medical examiners. (3) Nomination of examiners. (4) To act as chief examiner for the city of his appointment. The most important duty of the medical referee is the revision of all examinations that pass through the manager's office. This means that the medical record is carefully and thoroughly scrutinized. The referee approves all certificates of health and decides when medical reports should be returned to examiners for completion. The referee is at liberty to call for special reports, which are obtained for him by the manager. He acts upon the medical matters of these reports in the same way that he acts upon the applications and certificates of health.

The medical referee has the authority to release policies subject to medical restrictions. Because of this authority most policies are forwarded to the manager's office immediately upon receipt of the applications at the home office. On receipt of the policies at the manager's office they are promptly released in the "clean cases" and also in the cases where the information requested regarding the medical report has been received and is satisfactory. In other words, in the latter cases the policies are sent subject to information regarding the impairment. But when all the requirements have been complied with and the additional information is unsatisfactory or an adverse report has been received, the policies are held for further instruction from the home office. In some of these cases it is necessary to leave the final decision to the home office. When there is yet a possibility of clearing up the case policies are still held subject to further information, which the referee seeks to obtain.

The medical referee passes on the examiner of each medical report; in cases of irregular examinations, whether approved or disproved, the notation of his actions appears on the memorandum sheet attached to the application. On the memorandum sheet also appears the medical referee's actions regarding an examining physician who is not an appointed examiner of the company. The medical referee nominates examiners in the agency and has sufficient authority in such nominations that the manager can refer directly to him for temporary appointments.

The medical referee, by personal instruction, can make more efficient the work of the field examiner. Through the medical referee system the field examiners are brought into closer touch with the home office medical staff.

Dr. Layman, in conclusion, stated the advantages accruing from this system to be as follows:

(1) Advantages to the company: (*a*) Business is expedited, for policies are sent subject to medical restriction. (*b*) A larger per cent. of business will be done, either accepted or rejected. There will be less business held up, since the referee knows the company's requirements. He will, therefore, in his own examinations present the report of the risk in such conditions that it will be either accepted or declined. (*c*) Under the medical referee system time and labor is saved at the home office, as the referee will write examiners, asking for requirements. There is no limit to the number of applications that can be handled at the home office. (*d*) Under the medical referee system there is a better selection of medical examiners for the company and a better selection of risks, as very few bad risks will be accepted by the referee, and a careful selection of examiners promotes a better selection of risks. (*e*) The medical referee is a protector of the company's interests at all times in preventing bad risks from being accepted. Upon receipt of unfavorable information at the last hour from any source in regard to an applicant to whom a policy has recently been issued, the referee notifies the manager, who takes steps to prevent the delivery of the policy.

(2) Advantages to the manager's office: (*a*) The system materially facilitates the dispatch of business at the manager's office, as there is a quick release of policies; time is saved, the referee anticipating the home requirements. (*b*) The referee is in a better position to promptly secure additional information, either by correspondence or telephone. (*c*) The referee's action regarding just what application papers, etc., are necessary to return to the examiner for completion or revision is a great time saver for the manager's office. Otherwise, these would have to be acted upon by the home office and returned from there to the examiners. (*d*) The manager can consult with the referee regarding the company's position on border-line cases and impairments. (*e*) The manager is able to learn quickly what physicians may be used for emergency examinations. (*f*) The manager, with the referee's assistance, can usually calm the ruffled feelings of an irritated agent and convince him that the examiner has been fair. (*g*) The medical referee system minimizes bad risks. The advantages of this are apparent. In the first place it is always bad for an agency to get bad risks. Cancellation of policies on bad risks makes soliciting business in that place difficult. In the second place, if a bad risk becomes a death claim and is contested it is a bad advertisement for the agency and the company. (*h*) Under this system evils do not exist that formerly existed in the cities where the managing agencies were located. In many of these cities, before the medical referee system was established the company had three or four examiners, and there was considerable rivalry among them for the agent's favor. A conscientious and skillful examiner who had the unpleasant duty of declining several risks in succession would lose favor with the agent, and for future examinations he would be used very little, if at all. Applicants would be taken to an examiner who was probably less skillful, in the hope that impairments would not be discovered. Such evils are abolished under the medical referee system, the success of which is greatly due to the independence of the referee and examiners. The company insists on careful work by impartial and uninfluenced examiners, who are familiar with its rules, thus eliminating impaired risks.

Book Reviews.

PRINCIPLES OF HUMAN PHYSIOLOGY. By ERNEST H. STARLING, M.D. (Lond.), F.R.C.P., F.R.S., Hon. M.D. (Breslau), Hon. Sc.D. (Cambridge and Dublin); Jodrell Professor of Physiology in University College, London. Second Edition. With 566 Illustrations, 10 in Color. Price, $5.00 net. Philadelphia: Lea & Febiger, 1915.

IN comparing this with the first edition that appeared three years ago one notes a number of important changes. Although the text has been enlarged the number of pages has been reduced from 1423 to 1271. This has been accomplished by a slight increase in the size of the page and in the number of lines to the page. The use of a thin but opaque paper prevents the volume from becoming unwieldy, a serious disadvantage in a textbook. The same clearness and elegance of literary style that characterized the first edition are still evident. All the recent advances in physiology are fully incorporated in the new work. Particular mention may be made of the new sections dealing with the nutrition of the brain and with the innervation of the bronchi. The sections on voluntary muscle and on the circulation have been rewritten. In its general plan this work is divided into four books: I, dealing with General Physiology; II, with the Mechanisms of Movement and Sensation; III, with the Mechanisms of Nutrition, and IV, with Reproduction. At no time more than the present has there been a closer dependence of the practical phases of medical science upon the teachings of physiology. The physician realizes this perhaps more than the medical student, as he scans the pages of this book and notes the recent conceptions of such subjects as the hormones, the autonomic nervous system, the defense of the organism against infection, etc. As a guide to the practitioner in refreshing his earlier studies in physiology and as a complete modern text book on the subject for the medical student this book fulfils its purpose admirably.

CANE SUGAR AND HEART DISEASE. By ARTHUR GOULSTON, M.A., M.D. Cantab. Hunterian Society Medallist, 1912. Price, $2.00 net. New York: Paul B. Hoeber, 1915.

DR. Goulston has had much success in the treatment of heart disease by means of cane sugar and has published in this work the reasons for this treatment and the results. He certainly makes out a good case for this mode of treatment. While admitting that cane sugar treatment is no panacea for diseases of the heart, he holds that it is a valuable addition to our therapeutic armament against failing, irregular hearts. He further suggests that there is "something" in West Indian cane sugar which is absent from beet sugar, and asks the question: Is it of the nature of a coenzyme or activator or what? He further hazards the opinion that in the matter of diet, if more sugar derived from cane and less sugar derived from beet root were consumed a more satisfactory prophylaxis in the treatment of circulatory diseases would be attained. The book is at once instructive and suggestive and will well repay a careful study.

SCHOOL HYGIENE. By LEO BURGERSTEIN, Ph.D., LL.D. (Vienna). Translated by BEATRICE L. STEVENSON and ANNA L. VON DER OSTEN. With 43 Illustrations and diagrams. Price, $1.00. New York: Frederick A. Stokes Company, 1915.

THIS is a small volume of 188 pages and is divided into five parts. Part I deals with the schoolhouse, its general planning and erection, lighting, and ventilation and heating; with the classroom and its equipment, and with other rooms, grounds, and facilities of the school. Part II discusses the hygiene of instruction under the following headings: general considerations; number of pupils and curriculum; the hygiene of different school subjects; homework, examinations, etc., and boarding schools. Part III deals with instruction in hygiene and Part IV, with school diseases and medical inspection of schools. The hygiene of the teaching profession comprises the subject-matter of Part V.

STUDIES FROM THE ROCKEFELLER INSTITUTE FOR MEDICAL RESEARCH. Reprints. Volume XXI. New York: The Rockefeller Institute for Medical Research, 1915.

THESE studies comprise a great variety of subjects of which may be mentioned the etiology of Hodgkin's disease, the virus of poliomyelitis, the migration of the malarial parasites, the spleen in relation to hemolytic jaundice, carbohydrate metabolism, the chemistry of gluconeogenesis, the cultivation of human tissues, experimental operations on the pulmonary valves, studies on spermatozoa, paroxysmal auricular fibrillation, Allen's studies on diabetes, and pneumococcus infection and lobar pneumonia.

ON THE FUNCTIONS OF THE CEREBRUM: I. Symptomatological Differences Associated with Similar Cerebral Lesions in the Insane, by SHEPHERD IVORY FRANZ. II. Variations in Distribution of the Motor Centers by SHEPHERD IVORY FRANZ, with the assistance of J. DUERSEN STOUT. The Psychological Monographs. Vol. XIX, No. I. Princeton, N. J., and Lancaster, Pa.: Psychological Review Company, April, 1915.

THE first part of the monograph deals with the clinical histories and autopsy findings of a group of cases from the Government Hospital for the Insane. That less than 600 records out of over 3000 were complete enough to be of value for study is a commentary on our failure to make proper records of all hospital cases. The study is finally narrowed down to 38 cases and from these the conclusion is drawn. "In none of these collections of cases did there appear to be any definite correlation between the degree of the atrophy and the special form of the disease, and in the special discussions of the individual groups of cases it has been stated that no correlation between the degree of dementia (paretic, arteriosclerotic, senile, or precox) and the extent or the degree of atrophy was present."

The second part deals with a series of careful experimental stimulations of portions of the brain in monkeys. The extent of the arm and leg areas is determined and the localization and type of movement recorded. From his own experiments and those of other workers, Franz concludes that "the connections which are made by way of the cortical motor cells are not definite in the sense; for example, that there is a passage of an impulse from a Betz cell in the anatomically defined cerebral motor region to another particular efferent cell in the spinal cord, but that the connection is in special senses of the terms, promiscuous and irregular" that there are various pathways from the Betz cell, any of which may be used. Though one path may be commonly used, the same stimulus under new conditions may cause the use of another path, and so, a variation in response to the same stimulus. The work is carefully done and well presented.

THE HEALTH OF SCHOOL CHILDREN. Contributions from American Medical Journals, July, 1913, to July, 1914. Compiled by W. H. HECK, Professor of Education, University of Virginia, United States Bureau of Education, Bulletin, 1915, No. 4. Washington: Government Printing Office, 1915.

THIS is a valuable compilation of the articles pertaining to the health of school children that have appeared in American medical journals in the course of one year. Many of these articles have been contributed to the MEDICAL RECORD. The subjects deal with many aspects of pediatrics and educational hygiene. It is to be hoped that a similar compilation will be made for succeeding years.

THE OPERATIVE TREATMENT OF PULMONARY TUBERCULOSIS AND ARTIFICIAL PNEUMOTHORAX; by Prof. F. JESSEN, M.D.; Würzburger Abhandlungen, Vol. XV, Nos. 4 and 5, 1915. Price: Mk. 1.70.

IN this pamphlet of 118 pages Jessen describes the extirpation of the tuberculous lung as indicated by Garré, Quincke, Lowson, Doyen, von Herff, Tuffier, and others, but protests against pneumonectomy of the apices. Equally conservative are his expressions concerning opening and draining of cavities. He speaks enthusiastically of the compression of such cavities by artificial pneumothorax and considers this proceeding much more safe. The rest of the pamphlet is devoted to the description of the technique of this latter operation, of extrapleural thoracoplastic, the filling of cavities with paraffin, the cutting of the phrenic nerve to put the lung at rest, the ligation of the pulmonary arteries to cause shrinkage and formation of fibrous connective tissue, and lastly of Freund's operation consisting of opening the upper bony apertures. Jessen expresses his conviction that the future treatment of pulmonary tuberculosis will be a combination of climatic, chemical, and surgical means.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held October 21, 1915.

THE PRESIDENT, DR. WALTER B. JAMES, IN THE CHAIR.

The Form of Typhus That Is Endemic in New York and Has Been Unwisely Called "Brill's Disease."—Dr. NATHAN EDWIN BRILL spoke on this subject (see page 914).

Typhus Fever as I Have Observed It in Mexico, in England, and in This Country, in Its Clinical and Experimental Aspects.—Dr. JOHN F. ANDERSON, Director of the Hygienic Laboratory, United States Public Health Service, read this paper. He said that Dr. Brill had so exhaustively discussed the disease as it occurred in this country that nothing remained for him to say in regard to that type. There were others who were to take part in the discussion who had had a larger experience with the European type than he, because his experience had been confined to some 60 or 70 cases studied in England. He said he would confine himself largely to the disease as he had observed it in Mexico He had never noted any essential difference between typhus fever as seen by him in the United States, in Mexico and in England, except as regards the severity and mortality. The disease as seen by him in England had a case mortality of about 20 per cent.; the case mortality of the disease now recognized in America was not over 2 per cent. The case mortality in Mexico City showed in different years and in the native and foreign population considerable variation. In 1909 and 1910, among the patients in the Mexican General Hospital, the mortality was a little over 10 per cent., while in 1911 and 1912 it was nearer 5 per cent. The disease among the foreign population was much more severe as was shown by the fact that, according to the statistics of the American Hospital in Mexico City, there were treated, in that institution from 1888 to 1910, 144 cases of typhus fever of which 50 died, this being a case mortality of 34 per cent. The Mexican physicians ascribed to it a mortality of about 20 per cent. It was but natural that many of the mild cases escaped observation and did not come under the notice of the physicians or health authorities, while the severe cases were seen and in this way the case mortality rate was increased over the true figure. The disease was present in England, Ireland, certain parts of Europe, the central portion of northern Africa, in the temperate portion of Asia, and other portions of the Eastern Hemisphere. In the Western Hemisphere it occurred as a mild type of the disease in practically all of their larger cities as far west as Milwaukee and as far south as Atlanta. It also occurred in certain sections of the Republic of Mexico and of Central America. It had been observed in Mexico for years that typhus fever never prevailed below an elevation of 5000 to 6000 feet. Even when persons came from the higher altitude during the period of incubation and developed the disease after reaching the coast, or as called by the Mexicans the "true caliente," the disease did not spread. The inability of typhus fever to spread in the lower altitudes of Mexico or of other tropical and subtropical countries and its lessened prevalence in summer and fall was, he believed, due to the effect of the higher temperature on the transmitting insect, the body louse or pediculus vestimenti. He and Goldbuyer were the first to call attention to the adverse effect of temperatures higher than 20 C. on the longevity of the body lice and their observations were confirmed by Wilder. Since they now knew that typhus fever was transmitted by the body louse and knew the effect of temperature on the life of the insect, they were able to anpreciate the influence of the higher temperatures on the prevalence of the disease and to know why the disease was less prevalent in summer and fall and why in tropical and sub-tropical countries it never prevailed except above a certain altitude. Dr. Brill had reported having observed 254 cases of so-called Brill's disease, which was now known to be typhus fever, in the wards of Mt. Sinai Hospital between the years 1896 and 1910; 18 cases had been reported by Louria at the Jewish Hospital, Brooklyn, during the summer and fall of 1910; cases had been reported in other hospitals in New York City, as well as from Chicago, Milwaukee, Indiana, Virginia, Washington, Atlanta, Providence, Boston, and other places. It was evident that typhus fever, instead of having been completely eradicated from the United States, was still present. The demonstration of the endemic presence of typhus fever in the United States should require American sanitarians to recognize the persistence of the problem of which they had hitherto been unaware and to be on their guard against a disease that might at any time assume epidemic prevalence and virulence. All the efforts at prevention were centered upon the louse and these efforts might be broadly grouped under the following headings: (1) Measures for the reduction of lice infestation among the population in general. (2) The destruction of all lice and their eggs found on the bodies, clothing, bedding, and surroundings of all cases of typhus, typhus-suspects and contacts. (3) The adoption of measures by persons in the vicinity of cases of typhus to reduce or prevent the possibility of their being bitten by lice. (4) Inoculation with the mild type of the disease by persons contemplating entering localities where the disease was prevalent. Should Plotz's work be confirmed, this might be substituted by the use of a vaccine prepared from the typhus fever germ.

Pathogenesis as Demonstrated in the Pathological Laboratory of the Mount Sinai Hospital.—Dr. PETER K. OLITSKY stated that in response to the kind request made by the president of the Academy, he was presenting some of the conclusions that were contained in the publication made by Drs. Plotz, Baehr, and himself. He said that the organism was a small Gram-positive bacillus which grew only under anaerobic conditions. It was found in 100 per cent. of the epidemic typhus cases cultured before the crisis and 53 per cent. of the endemic cases. In two cases the blood cultures were positive twelve and thirty-six hours after the crisis. The earlier in the disease the blood culture was taken, the more often was it positive. The organisms were more abundant the more severe the case. The highest figures found were in two fatal cases of epidemic typhus. Antibodies against the organisms were found in the blood of typhus fever patients or in animals in which the disease was produced experimentally. There were found also complement fixing bodies, agglutinins, precipitins, and opsonins. These antibodies were usually absent when the fever was present and were present to a small extent at or shortly after the crisis. The greatest concentration was found from five to twelve days after the crisis. The crisis was not due to a sudden destruction of bacteria, but rather to the results of the activities of the cells. It was probable that the bacteria were gotten rid of by phagocytosis. Complement fixation tests were positive in 71 per cent. of the cases after the crisis. They were negative when tests were made with the serum of patients suffering from other diseases or with the serum of typhus fever cases tested against other organisms. Agglutinins were present in 92 per cent. of the cases after the crisis. In numerous control cases no agglutinins were found. The serum of typhus fever cases tested with organisms other than the typhus bacillus did not give an agglutination reaction. Precipitins were found in 73 per cent. of the cases after the crisis. In monkeys with experimental typhus fever, antibodies were found the same as in man. Eighty-three per cent. of the monkeys which reacted to the typhus virus showed positive agglutination and complement fixation tests. In guinea-pigs, only opsonins were found. In cases of endemic typhus the most marked antibody reactions were found in cases with negative blood cultures. Antibodies could be produced in a few monkeys by inoculation of the organism, but they were not immune to the virus of typhus fever. Antibodies have been found in the serum of several patients who have come closely in contact with typhus fever patients, although they did not present the clinical picture of the disease. Blood cultures were made in 24 guinea-pigs that were inoculated with blood from typhus fever patients. In one-third of them, the typhus bacillus was isolated. Positive results were also obtained in one monkey which had been inoculated with blood from a typhus fever patient. In guinea-pigs, the organisms were found more often the earlier the blood culture was taken and the more severe the disease was. In one animal a positive blood culture was obtained twenty-four to thirty-six hours after the crisis, corresponding to the period of infectivity of the typhus virus as determined by previous observers. It was found that blood from typhus fever patients which contained no bacilli or only very few bacilli, was not infective for animals. Typhus blood in which bacilli were more numerous, was infective for animals. This was of the greatest importance in linking the bacillus with the etiology of

typhus fever. Finally, Dr. Olitsky said they have succeeded in finding a febrile reaction like that in typhus fever by injecting a guinea-pig with an emulsion of live typhus bacilli from a case of epidemic typhus fever. In one guinea-pig the organism was recovered from the blood at the height of the febrile reaction. A typical typhus fever could not be produced by injecting organisms from endemic cases. The experimental studies show that the relation of the organism to typhus fever in animals had its counterpart in man, that it was possible to reproduce the disease in animals with the bacillus of epidemic typhus, that at the height of the disease in such animals, the organism can be obtained from the blood, and finally that typhus blood is only infectious when it contains a sufficient number of bacilli.

Dr. G. A. FRIEDMAN said that while in active practice in a provincial town of western Russia he had had the opportunity of observing three epidemics of typhus fever. As modern preventive measures were never undertaken in that community, he constantly saw endemic cases of the disease which ran a mild course with a very low or no mortality. Thus being well acquainted with endemic typhus it was not a difficult task for him to correct Dr. Brill when he first heard his paper in 1910 and in later discussions on the theme to maintain Brill's disease was nothing else but typhus fever. In a paper read before the Section on Medicine he stated the following conclusions: 1. Typhus fever occurred sporadically in many regions. 2. Mortality from typhus fever no longer reached the high figures quoted by some observers of the disease. 3. Typhus was little contagious wherever good ventilation, abundance of light, and good hygienic conditions existed. 4 Epidemics of typhus fever might occur at infrequent intervals even where the disease was endemic. 6. Brill's symptom complex was identical with mild and moderately severe cases of typhus fever. Dr. Brill, not agreeing with his conclusions, said that the discussion of such an important matter should be brought up before the whole Academy. He was glad that he had shown he had finally come to agree with the views first expressed by him and at that time violently opposed by him. His clinical observations gave the stimulus to the work of Dr. Anderson and Goldberger, whose results combined with Dr. Noguchi's and Dr. Libman's bacteriological excellence had served to establish firmly the etiology of the disease by Drs. Plotz, Olitzky, and Baehr. This sequence was shown by the fact that during the period of about fourteen years when Dr. Brill's observations were going on, not a single case of experimental work had appeared in press in regard to this disease and only in February, 1912, nine months after his paper was read, and five months after it was published, they first heard about the well known cross immunity tests. Dr. Friedman said he did not wish to speak about it to demonstrate his priority in identifying Brill's disease with typhus fever, but to show once more that the clinicians' observations at the bedside meant very much indeed. And even if good fortune had not blessed them with such skilled laboratory investigators, the clinicians would not have gone bankrupt after all, as according to the latest report of Dr. Plotz and his co-workers, the bacillus typhi-exanthematic was found in 53 per cent. of the endemic cases only. For the practitioner of medicine, the symptomatology and not laboratory findings still remained the mainstay of diagnosis, and Dr. Brill deserved all credit for giving an extremely well observed picture of endemic typhus fever and he, therefore, would proceed to discuss briefly the epidemiology of the infection. In a given locality epidemic typhus fever, when it had not been present in the near past or ever, was never present unless the cause was an exogenous one, *i.e.* the contagion being imported. In such a community the epidemic spread more rapidly than in a community where outbreaks occurred at frequent intervals. These cases ran a more severe course, and the mortality was higher. It was then possible to trace the first case, especially in the province. An epidemic broke out with few exceptions in the fall (October or November) and reached its acme in February or March when it started to decline and with the first warm days the epidemic died out. Somehow there was a tendency for the contagion to remain in many regions of the world in an attenuated state. In such a community one saw constantly mild or moderately severe cases of typhus fever; in other words the disease had become endemic and in large cities the origin of an epidemic from endemic cases was frequently overlooked for the simple reason that they remained unrecognized even by very good observers. From the fact that in some places typhus fever died out completely and in others it remained endemic, one must assume a predisposition of many localities to preserve the contagion in a modified form. From such cases an epidemic might be expected at any time. It was therefore evident that if an epidemic of typhus fever broke out in a community where the disease was endemic, the actual origin of the first case remained unknown. It was also impossible to state why the endemic cases did not lead more frequently to epidemics in overcrowded dwellings of the large cities. In endemic regions one saw cases of typhus fever in all seasons of the year, though in fall and winter the moderately severe cases were more noticeable, while in spring and summer the mild cases predominated. Thus in epidemic and endemic typhus fever, cold seemed to favor not only the spread of the disease, but likewise its severity. As a rule the course of the disease was mild among children even in epidemics.

Dr. E. LIBMAN said that Dr. Brill had forgotten to mention two other fatal cases of endemic typhus fever in which he had made autopsies. He mentioned these two cases not so much because of the influence on the mortality figures as that brought the mortality only up to three-quarters of one per cent., but because in both of them the bone marrow of the femur was red. This feature of typhus fever was first noted by Dr. Welch who has expressed the view that possibly the organisms multiply in the bone marrow. The suspicions that have been expressed, that the organism of Dr. Plotz might be a secondary invader, could be easily dismissed. Those who had had such an idea had brought into the discussion the findings of secondary invaders in yellow fever and in hog cholera. People had thought that in scarlet fever there was a constant secondary invader, but it had been shown that streptococci were found in the blood of scarlet fever only in cases which had a definite primary focus for invasion, which focus was generally in the nose or throat. Cases that died of fulminating scarlet fever showed no streptococci in the blood or organs. As regarded yellow fever, it was now known that the disease was produced by a filtrable virus. Sanarelli found a paracolon bacillus occasionally in the blood during life, but generally only post-mortem, and the organism was generally found associated with other organisms. Reed and Carroll did not find this organism present in the blood during life or in the organs of the fatal cases. Other observers had found colon bacilli or paracolon bacilli mixed with other organisms. There was no single true secondary invader in yellow fever. Hog cholera was now believed to be due to a filtrable virus. Originally there was found a paracolon bacillus after death, but it had now been found that this organism was not found alone and in other cases colon bacilli are found. The bacilli have not been found in the blood during life. They knew then of no disease which had a constant secondary invader. The organism described by Drs. Plotz, Baehr, and Olitzky was found regularly in the blood of epidemic typhus fever and in half of the cases of endemic typhus fever. It was found more often and more abundantly in the epidemic cases than in the endemic cases. The organisms from the epidemic cases were found to be virulent, those from the endemic cases were not. Sufficient other evidence was contained in the published work on the subject, but attention should be called here to a point of considerable interest. In the part of the work done by Dr. Olitzky one found that, in the endemic cases of typhus fever, he found the most marked complement fixation and agglutination reactions in the twenty cases that had negative blood cultures. Most of these cases were cultured within five days before the crisis. As the organism was not in the blood at that time, it was evident that it either was in the blood before that time or was in the organs, otherwise reactions would not have been obtained against the organism. This was definite proof that the organism could not be considered a secondary invader but was a primary invader. Those who still doubted the organism will have to contend that there were two organisms which caused typhus fever and that this is one of them. No other disease has been found to be due to more than one organism. The first appearance of the complement fixing bodies and other antibodies after the crisis was to be explained by the remarkable studies of Dr. Richard Weil on pneumonia. In pneumonia, antibodies did not appear until after the crisis. By a set of ingenious experiments, Dr. Weil showed

that during the disease the antigen was present in such large amounts that it bound the antibody; that after the crisis with the disappearance of the antigen, the antibody could be found. As regards the bacteriology of typhus fever in Serbia, Dr. Libman announced that he had a letter from Dr. Baehr in which he states that the blood cultures in the very first two cases of typhus fever that Dr. Plotz and he studied in Belgrade, showed the typhus bacillus. In the first case the blood culture was taken on the fifth day; in the second case on the tenth day. Although both were mild cases, the number of organisms found was large. In fact, the number of organisms found in the case cultured on the fifth day was larger than that of any case that has so far been studied. This gave additional proof that the bacteriemia was more marked early than late. The probable reason why the investigators, who were studying typhus fever in Serbia before the arrival of Drs. Baehr and Plotz, did not get the organism in any number of cases was that the serum which they used was not favorable for the growth of the organism. Dr. Zinsser recovered the organism in one case, Dr. Hopkins in one case, and Dr. Anderson isolated the bacillus from the blood of infected guineapigs. As regards the question of immunization, Dr. Libman believed it would be best before adopting the method suggested by Dr. Anderson, namely, by injecting a patient with the virus of Brill's disease, to first try the injection of dead bacilli, then of sensitized living bacilli, and, finally, if it should be found necessary, small numbers of live bacilli from the endemic cases, these bacilli not being virulent. It had never been demanded that to prove that an organism was the cause of the disease one would have to prove that one could immunize with the organism. To ask for this proof would mean that they would have to add a fifth postulate to the four announced by Koch which would say that no organism would be considered the cause of the disease unless one could at the time one announces the discovery of the organism, also announce the method of immunization against it, or cure of the disease. While the experiments of Dr. Anderson were of great interest, it must be noted that his inoculations of virus were all made intraperitoneally. Theobald Smith stated, "Immunity that can be established toward a subcutaneous dose of the virus may fail completely to protect against a much smaller intraperitoneal dose." Human beings acquired typhus fever through the skin. Apart from that, the organisms used by Dr. Anderson were not virulent, and from results of the immunity experiments on animals, one would draw no binding conclusions as regards the efficiency of vaccination in human beings. It had been found by Metchnikoff and Besredka that chimpanzees could not be immunized against typhoid fever with dead bacilli; only sensitized living bacteria would immunize. In human beings remarkably good results were being obtained in the prophylaxis of typhoid fever by injections of dead bacteria. It would be best at the present time to follow the advice given by Leishmann in connection with typhoid fever, that was to make careful studies in human beings.

PHILADELPHIA NEUROLOGICAL SOCIETY.

Stated Meeting Held October 22, 1915.

A Patient with Symptoms Suggestive of Rhizomelic Spondylosis.—Dr. JAMES HENDRIE LLOYD reported this case which occurred in a man about fifty-five years old who for some time had complained of shooting pains in the lower extremities and who presented dorsolumbar kyphosis, with restricted mobility at the hip-joints, preserved perhaps increased knee-jerks, abolished Achilles jerks, inequality of the pupils with sluggish light-reaction and a negative Wassermann reaction. X-ray examination disclosed coalescence of some of the vertebræ and the presence of osteophytic processes.

Brain Tumor in the Parietooccipital Region Causing Homonymous Hemianopsia.—Drs. J. H LLOYD and MAX H. BOCHROCH reported this case. The patient suffered from headache and he had causeless vomiting, without changes in the ocular fundus. He had a tendency to pitch forward in walking, and the Wassermann reaction yielded a negative response. Great relief followed cerebral decompression, but gradually the symptoms progressed and terminated fatally. Autopsy disclosed a new-growth of considerable proportions in the parieto-occipital region of the brain.

Unusual Form of Myotonia. — Dr. FRANCIS X. DERCUM presented this case. The patient was a boy nine years old who some months following an attack of mumps developed swelling of one knee and later difficulty in walking, and in time also in the use of the upper extremities. Any attempt to perform a given act was attended with spasm of the muscles involved, which did not relax on persistent use as in Thomsen's disease. The knee-jerks were increased, and on electrical stimulation anodal closure contraction was as great as kathodal closure contraction. The disorder was thought to be due to a diseased state of the musculature. In the discussion Dr. Charles K. Mills suggested that the case might belong in the group of extrapyramidal lesions of the nervous system affecting the tonectic mechanism.

Dr. DERCUM exhibited also a man twenty years old who presented symptoms indicative of involvement of the nuclei of all of the cranial nerves with the exception of the pneumogastric. One of the earliest symptoms was pain in the right ear, and later a discharge from the same ear. After a time enlargement of glands on the right side of the neck was observed, and these were removed, but nothing could be learned as to their histologic character. Soon there developed complete internal and external ophthalmoplegia on the same side, with immobility of the eye and ptosis, facial paralysis, with loss of sensibility in the distribution of the upper branches of the fifth nerve, difficulty in swallowing, loss of taste on the right side of the tongue, with atrophy and deflection of the tongue to the right, probably impairment of smell, and beginning atrophy of the optic disc. A neoplastic mass was found in the nasopharynx. It was thought there might be a metastatic lesion or a degenerative process involving the nuclei of the respective nerves, but in the discussion Dr. William G. Spiller suggested that the symptoms might be explained by a metastatic growth at the base of the brain involving the trunks of the several nerves involved in the course or at their points of exit from the skull.

Drainage of the Cerebrospinal Fluid as a Factor in the Treatment of Nervous Syphilis.—Drs. S. F. GILPIN and THOMAS B. EARLY read this communication. They pointed out that the inefficiency of treatment in cases of syphilis of the central nervous system is explained by the fact that the drugs ordinarily employed and administered by the mouth or into the subcutaneous or muscular tissues or into the bloodstream do not reach the nerve tissues on account of their failure to pass through the choroid plexuses into the celebrospinal fluid. With a view to bringing about such a passage of the active medicaments the author reasoned that such a result might be effected by removing cerebrospinal fluid by lumbar puncture to such a degree as to lower the pressure in the meningeal sac sufficiently to favor the passage of therapeutically active substances from the blood into the cerebrospinal fluid. Influenced by this reasoning they undertook to treat cases of tabes and paresis with inunctions of mercury in conjunction with withdrawal of maximum amounts of cerebrospinal fluid, and the results thus far in a small number of cases have been successful and encouraging, as manifested by disappearance of previously positive Wassermann reaction, diminution in the number of cells in the cerebrospinal fluid and subjective and objective symtomatic improvement.

Endothelioma of the Temporooccipital Lobe with Partial Motor Aphasia. — Drs. WILLIAM G. SPILLER and GEORGE P. MULLER reported this case. The patient presented symptoms of a brain-tumor without localizing indications, but when the skull was opened a telangiectatic state of the pia nater was found. Some of the vessels were ligated, but the patient survived only a few days. Post-mortem examination disclosed a neoplasm in the temporooccipital region and this on histologic examination proved to be an endothelioma. Death had resulted from cerebral hemorrhage secondary to ligation of the blood-vessel.

Observations in the European War Zone.—Dr. DANIEL J. MCCARTHY gave this informal account. He pointed out that by reason of changed conditions of warfare a new group of diseases is being observed. The greatest harm is done by shrapnel, which in addition to any primary injury usually gives rise to infection, the sequels of which cannot be forseen or anticipated. It was found better to permit such wounds to remain undisturbed for a while rather than to make attempts to remove foreign materials carried into the wound,

contenting oneself for the time being merely with cleansing the superficial area. Bullet-wounds on the other hand are usually clean and may heal with remarkably slight manifestations. Apart from direct injuries of nerve-tissue there occur a great many cases of what must be described as disorders attributable to concussion. Not rarely injuries result directly and indirectly from the force of an explosion without apparent superficial lesion. At times at field and base hospitals the cases are so numerous and the pressure of emergency work so great that little time is afforded for full investigation, thorough study and complete records.

Verbal Amnesia and Alexia.—Dr. ALFRED GORDON reported this case and exhibited the specimen. The patient had difficulty in naming objects and when he made a mistake he was at once aware of the error. He had no difficulty, however, in repeating names mentioned to him, and here again he appreciated their proper application. He could read letters but not words. Death resulted and autopsy disclosed a neoplasm of the left occipital lobe.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

SENESCENCE AND REJUVENESCENCE. By CHARLES MANNING CHILD. Published by The University of Chicago Press, Chicago, Ill.; 481 pages. Price $4.00.

ORAL SURGERY. By TRUMAN W. BROPHY. Published by P. Blakiston's Son & Co., 1012 Walnut Street, Philadelphia, Pa. With 909 illustrations, including 39 plates in colors; 1090 pages.

THE CLINICS OF JOHN B. MURPHY, M.D., at Mercy Hospital, Chicago, October, 1915; 1025 pages. Published bi-monthly by W. B. Saunders Co., Philadelphia and London. Price, per year, $8.00; foreign, 35 shillings.

WISH-FULFILLMENT AND SYMBOLISM IN FAIRY TALES. By Dr. FRANZ RICKLIN of Zurich. Published by Nervous and Mental Disease Publishing Company, New York; 89 pages. Price, $1.00.

MANUAL OF EMBRYOLOGY. By A. MELVILLE PATERSON. Published by Oxford University Press, Warwick Square, E.C. London; 391 pages. Price, $2.75.

HOW TO LIVE. By IRVING FISHER, and EUGENE LYMAN FISK. Published by Funk & Wagnalls Company, New York and London; 345 pages. Price, $1.00 net.

VAGOTONIA. A Clinical Study in Vegetative Neurology. By Dr. HANS EPPINGER and Dr. LEO HESS. Published by Nervous and Mental Disease Publishing Company, New York; 92 pages. Price, $1.00.

THE HEALTH-CARE OF THE GROWING CHILD. By LOUIS FISCHER, M.D. Published by Funk & Wagnalls Company, New York and London; 341 pages. Price, $1.25 net.

RULES FOR EMPLOYEES OF THE BUREAU OF PREVENTABLE DISEASES. Including those for All Employees. The Department of Health of The City of New York; 106 pages.

A MECHANISTIC VIEW OF WAR AND PEACE. By GEORGE W. CRILE. Published by The Macmillan Company, New York. Illustrated; 104 pages. Price, $1.25.

DIAGNOSTISCHE UND THERAPEUTISCHE ERGEBNISSE, DER HIRNPUNKTION. Von Dr. WALTER PINCUS. Published by August Hirschwald, Berlin, 1916; 211 pages.

QUANTITATIVE LAWS IN BIOLOGICAL CHEMISTRY. By SVANTE ARRHENIUS. Published by G. Bell and Sons, Ltd., London; 159 pages. Price, 6/- net.

Therapeutic Hints.

Emetine in Bronchial and Pulmonary Affections.—At a meeting of the Société Médicale des Hôpitaux, July 5, 1915, M. Guinon and Mlle. Pouzin reported that they had obtained good results in the treatment of bronchial and pulmonary affections in infants and children by means of emetine. The daily dose in infants was 0.005 gram; in children up to five years it was 0.01 gram, and in children over five years it was 0.02 gram. If the polypnea and cyanosis indicated a danger of bronchial asphyxia the authors used in addition subcutaneous injections of oxygen in doses of 200 to 500 c.c.—*Presse Médicale.*

Hexamethylenamine Internally for Ophthalmia.—Kirkpatrick has successfully used hexamethylenetetramine in septic inflammations of the cornea and conjunctiva by administering 15 grains every four hours. The drug is excreted by the lacrymal gland. He finds it of use also in the treatment of ordinary colds.—*The Indian Medical Gazette.*

Salvarsan for Schistosomiasis.—Post reports that there was a marked change in his case from the date of administration of salvarsan, and that Mann of the U. S. Navy has had similar experience in the use of salvarsan in schistosomiasis.—*U. S. Naval Medical Bulletin.*

Frostbite.—The theory of Noesske, that gangrene may often be avoided in severely crushed and lacerated wounds of the extremities by deep incisions in the injured part, allowing the escape of venous blood and the entrance of arterial blood, was applied by A. Wittek (*Dermatologische Wochenschrift*) to cases of gangrene due to freezing. Within twenty-four hours of the application of the treatment he has seen the line of demarcation descend and the blue-green, glassy appearance of the part clear up. The fever promptly receded and no phlegmon formed. He used collargol wet dressings for the first three days, then a mild ointment. He recommends the method highly. "One is pleasantly surprised at the slight extent of the necrotic area." E. Bundschuh also praises the excellent results of the Noesske treatment. In addition to the deep incisions, he applies the cupping glass twice the first day and once each day thereafter, and prevents the adhesion of the wound edges by the interposition of gauze dipped in sterile oil. Lukewarm baths for the affected member were also very effective. In superficial freezing the incisions need not be so deep, but they should always be deepest on the ball of the finger, as this part is always in the greatest danger.—*Journal of Cutaneous Diseases.*

Craving for Alcohol.—

MILK-BORNE SEPTIC SORE THROAT—A NEW HEALTH PROBLEM.*

BY HERMANN M. BIGGS, M.D.,

NEW YORK.

SEPTIC sore throat, while probably not a new disease, has at least appeared in a previously unrecognized form in this country within the last few years. A number of extensive epidemics have occurred, all resembling each other closely in character and due, as a rule, primarily to widespread milk infections.

Previous to the Boston epidemic in 1911, which was carefully studied and reported by Winslow, no milk-borne epidemic of tonsillitis or similar throat disease had hitherto been reported in this country. Similar epidemics were not, however, uncommon in Great Britain, as Swithinbank and Newman[1] in 1903 stated that "it is safe to assume that a year never goes by in which there are not outbreaks of sore throat or tonsillitis due to milk or cream." As early as 1875 the medical officer of South Kensington[2] reported twenty cases infected from a common cream supply, while at Aberdeen in 1881,[3] 300 cases occurred in 90 families supplied by a single dairy. As it is not the purpose of this paper to give in detail the history of the English epidemics, only a brief citation of the more important ones will be made. From 1880 to 1905 there occurred ten epidemics, fulminating in character, which presented clinical pictures so at variance with the well-known types of sore throat and tonsillitis previously observed as to attract widespread interest and comment.

Notable among these were the epidemics occurring at Rugby,[4] Dover[5] and Edinburgh,[6] at Rothesay,[7] Hackney[8] and Lincoln,[9] at Bedford,[10] Woking,[11] Paisley[12] and Colchester.[13] This list, incomplete as it is, is sufficient to establish the fact that septic sore throat has been known in Great Britain for over thirty years.

In the Boston[14] epidemic of 1911 the records of over 1400 cases were collected, of which between 1100 and 1200 cases occurred in Boston, Brookline, and Cambridge between April 22 and June 6. At about the same time 392 cases occurred in Hudson, Marlboro, and Southboro—twenty miles to the west of the Boston district—between March 27 and June 5. This smaller outbreak apparently antedated the Boston epidemic and was complicated with it. It consisted of two separate outbreaks, the height of the first being in the week of April 3 and of the second in the first two weeks of May. The source of the first outbreak was not determined; the second was evidently the result of the same milk infection which caused the major epidemic in Boston, namely, the milk from the Deerfoot Dairy. Forty-eight deaths were ascribed directly or indirectly to the disease, most of which occurred in the later periods of life as the result of complications which were numerous.

About 70 per cent. of the cases occurring in the Boston epidemic were supplied by milk from one dairy. In his report, Winslow concludes that "the milk from this dairy was the means of transmitting this disease, but it was probably infected by human beings and not by dairy cows, although no acute cases of sore throat were found among dairy employees," and he was convinced that a carrier case presumably infected the milk.

In December, 1911, and January, 1912, an extensive outbreak occurred in Chicago,[15] described by Heineman and by Capps and Miller. These authors estimated that over 10,000 cases occurred, a majority of which were receiving milk from one dairy. It is stated that an epidemic of mastitis occurred among the cows supplying the milk to this dairy during the winter months. Dr. D. J. Davis of Chicago, who made bacteriological examinations of the milk, stated that he found a streptococcus identical in morphology and cultures and in pathogenicity with the culture obtained from a human case, complicated with arthritis. Dr. E. C. Rosenau, who also made bacteriological studies in this outbreak, says "the fact that milk so modified streptococci is an additional indication of the important part it may play in epidemic sore throat. It is not possible to determine whether the streptococci in such epidemics are exclusively of bovine or human origin—they may be both. Milk drawn in a sterile way from normal cows may contain virulent streptococci and pneumococci; hence, certified milk, while surely less contaminated than ordinary milk, may contain pathogenic bacteria, and the advisability of pasteurization even in this case should be considered, especially during the season of sore throat."

Coues reported an epidemic of 227 cases that occurred in Boston[16] in February, 1912. With the exception of twenty-one cases, the milk supply of all was ascertained and carefully investigated. It was found that 48.5 per cent. of all the cases received milk from one dealer, and an examination of the employees of the dairies supplying him disclosed several cases of septic sore throat, from four of whom practically pure cultures of streptococci were obtained. Most of the milk was unpasteurized.

In Baltimore[17] during the months of February and March, 1913, a similar outbreak occurred with a total of 602 recorded cases. It is certain, however, that the total number of cases greatly exceeded this estimate. In his epidemiological study of the outbreak, Frost states that "the extent of the epidemic can only be surmised. It may be estimated that certainly not less than 1000, and perhaps as many as 3000 cases, occurred in this outbreak."

*Read at a meeting of the Practitioners' Society of New York, October 8, 1915.

The majority of the cases developed between February 1 and March 20. Sixty-five per cent. were supplied with milk from one dairy, which dairy supplied only 3.3 per cent. of the milk sold in Baltimore. Twenty-eight deaths occurred during this outbreak, chiefly as the result of secondary infections. Thirteen of these deaths were caused by peritonitis, seven were cases of general septicemia, four septic pneumonia, two erysipelas, and one appendicitis. The milk causing this outbreak was pasteurized by the "flash" method.

A number of articles on this epidemic were published, the most extensive being that by Frost and Stokes, and Hachtel. It is stated in their reports that "either pathogenic germs were introduced into the milk by some infected person who had had to handle the milk, or were derived from the udders of some of the cows who produced it." A veterinary examination made after the beginning of the outbreak failed to show the presence of mastitis in any of the cows in this dairy, although the authors believe this to be the more probable source of infection. The system of "flash" pasteurization used by the dairy was found to be inefficient. They isolated a streptococcus from the peritoneum and from the milk glands of one of the cows, which closely corresponded with cultures from the throats of patients suffering with the disease. An organism of *Streptococcus epidemicus* type was also isolated from the raw milk shipped to the dairy—the milk which probably caused this epidemic. Further investigation also showed one cow whose milk contained a large number of pus cells. Cultures from this milk were contaminated by colon bacilli, so that no pneumococci or streptococci could be obtained. Cultures from the throats of the family and employees, however, showed that one driver was a carrier, although there was no history of sore throat. An examination of the suspected dairy farm disclosed the presence of several gargety cows.

Contemporary with this outbreak, Mann reported the occurrence of an extensive epidemic at Concord, N. H.[18] Records of 472 cases were obtained but, in the opinion of the author, over 1000 cases occurred. A remarkably large number of the people affected with the disease obtained their milk from a common source—82 per cent. receiving milk from one dealer. Investigation of the milk supply developed the fact that there had been several recent cases of sore throat among the farmers supplying this dealer. Although the mortality was low, four deaths resulting from the disease, there were many complications, erysipelas, pneumonia, tonsillar abscess, and otitis media occurring most frequently.

In February and March and the first two weeks in April, 1913, a number of scattered cases of sore throat occurred among the inhabitants of the city of Cortland[19] and the village of Homer, and in the last week of April a constant increase in the number of cases appeared and a widespread epidemic rapidly developed. Between April 1 and May 9, 669 cases were reported, with 14 deaths—all the results of complications and all occurring in the later periods of life. Five deaths were due to peritonitis, four to erysipelas, two to pneumonia, two to heart failure, and one to edema of the lungs. This outbreak was carefully studied by North, White, and Avery. The following is from their report:

Summary.—1. Two epidemics of septic sore throat occurred simultaneously in May, 1913, in Cortland and Homer, N. Y., the two communities being three miles apart.

2. Over 70 per cent. of the cases in each community occurred among the patrons of a dairyman who was the only dairyman selling milk in both places and who supplied less than 7 per cent. of the total milk supply. Adjacent towns had no cases, and further, they received no milk from the suspected dairy.

3. Physical examination of the cows and microscopical examination of milk sediments showed the existence of acute udder inflammation in two cows in the herd of the suspected dairyman.

4. Bacteriological examination showed that cultures from the throats of four patients contained streptococci apparently identical with strains of streptococci obtained from milk slime from the two cows suffering from garget. Cultures from the throats of eight other patients contained streptococci of this same type, but differing by slight variations only in their carbohydrate fermentations.

5. The streptococci isolated from the milk slime from the two gargety cows and the throats of four patients in the present epidemic correspond in all respects to strains of streptococci isolated previously from three cows of another herd known to be suffering from garget, and from the milk slime from one cow supposed to be normal, but which gave an abnormal amount of slime.

In February, 1913, at Middlebury College, Middlebury, Vt.,[20] and in the vicinity, an outbreak of septic sore throat occurred which is reported by Dr. Eddy, the health officer of Middlebury. Over sixty cases of the disease occurred in the month of February with one death. The evidence of this outbreak strongly indicated that it was the result of milk infection, although the source of infection was not determined.

In New York State during a little more than a year past, three serious outbreaks have occurred and several smaller ones. Two of the serious outbreaks were characteristically epidemics of septic sore throat and the third was either an epidemic of scarlet fever and septic sore throat or an unusual type of septic sore throat.

The first occurred in Nassau County,[21] where 232 cases with two deaths were recorded in the village of Rockville Centre between May 30 and June 30—the majority of the cases occurring in the first two weeks in June. In 89 per cent. of these cases there was a definite history of the use of the milk from one dairy, although this milk supply constituted not more than one-fourth of the total used in the community. The first case in this outbreak reported on by Dr. Overton, sanitary supervisor of the State Department of Health, Dr. Krumweide of the New York City Department of Health, and Dr. Jacques, health officer of Rockville Centre, was the daughter of the woman who owned the dairy in question. The woman herself developed the disease as did also two of the milkers on the farm.

Inflammation of one-half of the udder was present in one cow in this dairy and abundant streptococci were found in the milk of another cow which had no outward signs of sickness. The epidemic quickly subsided when this milk was withdrawn from sale.

On August 14, 1914, the health officer of Easthampton[22] reported to the sanitary supervisor of the State Department of Health that septic sore throat was prevalent among the summer colony. Forty-six cases were discovered, all but one of which received milk from the Y—— dairy. Inquiry was made at the dairy, where it developed that one of the

helpers had been ill from August 4 to 7. On examination, his throat was still inflamed, and a culture taken on the 16th showed an abundant growth of almost pure streptococci. Exclusion of this helper from the dairy, and pasteurization of the milk for a limited period, resulted in the prompt subsidence of the epidemic. No evidence of infection of the udders of the cows was found.

An extensive and serious outbreak of septic sore throat occurred in Westchester County during[23] the spring of the present year. Mt. Vernon, Bronxville, and Tuckahoe were specially affected. The records of 900 cases were collected (many more undoubtedly occurred) between January 15 and May 1. Previous to February 15 there had been numerous scattered cases of this disease in this region. These suddenly increased markedly during the week of February 15 in White Plains, and the following week in Mt. Vernon. In the week of February 22 there were 130 cases in Bronxville and Tuckahoe; this was the height of the epidemic and the numbers decreased week by week until the middle of April when they practically disappeared. Fifty-eight per cent. of the cases were among females—a peculiar incidence characteristic of this disease in almost every outbreak previously reported. The cases were pretty evenly distributed at all age periods, as has also been commonly observed.

In the Boston epidemic, the milk outbreak, as in this instance, was preceded by prosodemic spread and was followed by a similar extension by contact. In the Westchester epidemic there was a question as to the possible relation of the milk of one dairy with the outbreak, as during the period when it was at its height, 63 per cent. of the cases in Mt. Vernon, Bronxville, and Tuckahoe were in households served by one dairy; while before and after that period only 44 per cent. were in such households. In White Plains during this same three weeks, 62 per cent. of the cases were receiving this milk against 52 per cent. for the period before and after. But as the company in question supplies about 45 per cent. of the total milk supply of these communities, the increased incidence was not marked. It suggests that a small milk and cream epidemic may at this period have been superimposed upon a general prosodemic spread. The symptoms of the disease were quite the same as those which ordinarily are present in septic sore throat. It was not an epidemic, however, of great severity.

This has been briefly reported by Dr. C.-E. A. Winslow, Director of Public Health Education, and Dr. L. W. Hubbard, Sanitary Supervisor of the State Department of Health.

In May, 1915, a very extensive outbreak of what was recorded as scarlet fever, combined with an epidemic of septic sore throat, occurred in Poughkeepsie[24] and vicinity. This epidemic was carefully studied by Dr. Meader and Dr. Winslow of the State Department of Health, and by Dr. North, who made a full report on the outbreak to the Poughkeepsie Academy of Medicine. There were 212 cases of scarlet fever and 296 cases of sore throat. The two diseases occurred at the same time and in the same district and were apparently closely related to each other. Thirty-four deaths occurred, the larger percentage of these occurring in the earlier period of life and in the majority of instances after a very short illness of less than one week's duration. In this epidemic the evidence of the agency of milk in the distribution of the infection was unquestioned, and apparently there were several milk epidemics interwoven with each other with great prosodemic extension of the disease.

The outbreak in this district was preceded by a smaller epidemic of less severity and extent in the adjoining rural districts, especially in the town of Rhinebeck, and it seems probable that the extension to Wappingers Falls, Poughkeepsie, Hudson River State Hospital, and the adjoining territory was direct from cases in these adjacent towns occurring earlier.

There are three possible assumptions in connection with this outbreak; the first one—which in my judgment is the probable one—is that an epidemic of scarlet fever and an epidemic of septic sore throat prevailed at the same time, both probably the result primarily of milk infections. The second assumption—which Dr. North has accepted—is that this whole outbreak was one of septic sore thoat of unusual severity; and the third assumption is that this was an epidemic of scarlet fever throughout, and that the sore throats were simply mild types of scarlet fever in which the eruption was not recognized or was transient, or was absent entirely as is sometimes the case.

In the latter part of May and early in June, 1915, an epidemic of 150 cases occurred at West Winfield.[25] All of the families affected received milk from the R—— dairy, where the source of infection was easily found. One of the milkers had been ill for several days previous to the outbreak but had continued to work, although feeling very weak. His throat and that of his wife, who was also ill, showed unmistakable evidence of severe septic infection. Here, again, the children and young adults were not seriously ill, being confined to the house, as a rule, only two or three days. Those in middle and later life suffered severely, relapses and complications being a frequent occurrence. The complications were those usual in septic invasion—erysipelas, polyarthritis, pneumonia, nephritis, suppuration of cervical glands, and otitis media.

The symptoms present in most of the septic sore throat epidemics have been fairly uniform, although the disease varies greatly in its severity, and single cases may present hardly a single feature in common with each other. Any series of cases, however, show at once the characteristic features. The onset of the attack, is usually rapid, is often accompanied by chill and is followed by a rapid rise in temperature to 103 to 105°. A severe headache and general muscular pain and soreness are present in the more severe cases. The appearance of the throat is variable. There may be only general redness extending over the tonsils, pharynx, and soft palate, much like the scarlet fever throat. Later small isolated patches of membrane may appear on the tonsils, or the appearance may be almost typical of an acute follicular tonsillitis. Later in many cases there is an extensive pseudomembranous exudate, strongly simulating diphtheria. Frequently one tonsil is first infected and then the other. The cervical lymph nodes are almost always more or less involved and often are very much swollen. The first period of the disease lasts from three to five days and may be followed by rather rapid recovery in the mild cases or by secondary complications which are numerous and frequently severe. Marked prostration follows in all of the severe cases.

The commonest complications are peritonsillar abscess and suppuration of the cervical glands. Extension of the inflammation to the nose and ear

sometimes occurs, although the deeper tissues about the neck are more frequently affected. Diffuse cellulitis of the neck is common. More serious complications occur, the result of general infection. Of these perhaps the commonest are polyarthritis, erysipelas, nephritis, pneumonia, pleurisy, pericarditis, septicemia, peritonitis. The majority of deaths have occurred in comparatively old people from complications, the deaths in children being rather infrequent. The convalescence is unusually slow and tedious.

In all outbreaks a long chain streptococcus has been found which has nothing to specifically identify it or make possible the positive differentiation from other stains of streptococci.

It is quite clear that the only means of prevention of this disease lies in universal pasteurization of the milk supply used for drinking purposes. It would seem probable from such evidence as we have that the milk may be infected primarily in the cow, or that it may be secondarily infected from someone handling the milk who has the disease, or is a carrier. It is also possible that mastitis may be produced in the cow by transmission of the infection to the udder from a human being, and it is also quite clear that the infection is frequently transmitted from one case to another. It is not at all clear, however, as to whether this disease as it prevails in epidemic form, is really a new disease or whether it has not been previously recognized. Certainly extensive epidemics, such as these described have not been reported as the result of milk infection in this country until the last four years.

Infantile Scorbutus.—J. Cornby reports the cases of twenty-six infants with this disease, none of whom were breast-fed or fed on fresh milk. He states that the most characteristic sign of incipient scorbutus is a pseudoparaplegia from pain. In addition to the use of fresh milk, boiled or not, he recommends the administration of orange juice in teaspoonful doses between feedings, and for children over a year old three tablespoonfuls of mashed potato during the day.—*Archives de Médecine des Enfants.*

SOME OF THE AUTOMATIC BALANCES IN THE HUMAN BODY.*

By RICHARD COLE NEWTON, A.B., M.D.,

MONTCLAIR, N. J.

CONSULTING PHYSICIAN TO THE MOUNTAINSIDE HOSPITAL, MONTCLAIR; LATE PRESIDENT NEW JERSEY STATE BOARD OF HEALTH; LATE CAPTAIN AND ASSISTANT SURGEON, U. S. ARMY.

EVER since the days of John Hunter it has been known that the controlling influence of the human will over the bodily functions and sensations may be immeasurably great. Tuke quotes Hunter in relation to the escape of the latter from the wiles of the mesmerizer. The mysterious power by which the will of one person is made by means of expectant attention or otherwise, temporarily subservient to that of another was then called animal magnetism, as I believe it is still designated by the so-called Christian Scientists.

Hunter, in his lectures on surgery in 1786-7, in treating of animal magnetism, relates an experience of his own. He had been persuaded to submit himself to the influence of the magnetizer, and speaks of the matter in this wise: "But considering that if any person was affected by it, *it must be by the imagination being worked up by the attention to the part expected to be affected*, and thinking that I could counteract this, I went, and acordingly when I went I was convinced by the apparatus that everything was calculated to affect the imagination when the magnetizer began his operations, and informed me that I should feel it first at the roots of my nails of that hand nearest the apparatus. *I fixed my attention on my great toe*, where I was wishing to have a fit of the gout, and I am confident that I can fix my *attention to any part until I have a sensation in that part.* Whenever I found myself attending to his tricks, I fell to working with my great toe, working it about, etc., by which means I prevented it (the attempted mesmerism) having any effect upon me."

Tuke says that the above excerpt really contains the gist of all that has been written on the influence of "expectant attention and the imagination" for the century following Hunter, and also added that the latter might have made as great a metaphysician as he was a physiologist. However this may have been, it seems wise that we should in the beginning of our study of the bodily balances, and the emotions, give a thought to the enormous power of the human will, which has hitherto for the most part, at least, been considered as an attribute quite apart from the physical characteristics of its possessor.

The tendency of modern teaching, however, points to a close, if not a causative relation, between the bodily functions and the will. Certainly the sensitive relations between the emotions and the body cells have received most striking proof from a number of recent investigations and many phenomena hitherto vaguely attributed to spiritual, or external influences, have been shown to be due to material changes in the state of the nerve cells. Cannon explains the so-called "ordeal of rice" as practised in India. It was early discovered that excitement or fear may inhibit the flow of saliva. Advantage was taken of this discovery in the trial of alleged criminals in the East Indies, and probably this primitive method of judicial procedure still obtains in that country. The suspected culprits were obliged to fill their mouths with the consecrated rice, which they were required to chew a short time

*Read before the Orange Mountain Medical Society.

and then spit out on the leaf of the sacred fig tree. If any of this ejected rice was found to be dry, the person who had chewed it without being able to insalivate it, was assumed to have had a "dry mouth" from guilty fear, and was adjudged guilty as indicted.

What is true of the salivary flow is also true of the secretion of gastric juice. And a curious difference between a hungry child with a gastric fistula and hungry dogs with gastric fistulæ has been noted. Pawlow showed that in the dogs the mere sight of the food caused the stomach juice to flow freely, whereas when the food was shown the boy, and then withheld, he grew angry and began to cry, and no gastric secretion appeared. Bogen also mentioned a case of a child with closed esophagus and a gastric fistula who sometimes fell into such a passion after longing in vain for food that even after he was pacified and given food no gastric juice would appear.

Another interesting case is cited showing the psychic inhibition of the gastric secretion in a dog with a gastric fistula and a side pouch of the stomach, which, as in Pawlow's experiments, opened only on the exterior of the body. In this animal "sham feeding"—that is, feeding by the mouth, none of the food reaching the stomach—excited a copious flow of gastric juice, a true psychic secretion, resulting from the pleasurable taste of the food. Five minutes of this sham feeding usually started a secretion lasting twenty minutes and amounting to 66.7 c.c. of pure gastric juice. When, however, a cat was brought into the room, the dog flew into a great fury. After the cat had been removed and his canine majesty had been calmed, he was given a sham feeding for five minutes. He was hungry and ate eagerly, but no gastric secretion worthy of mention followed; only 9 c.c. of an acid fluid, containing much mucus, was produced. On another occasion, after the flow of gastric juice had been well established by a sham meal, the cat was brought in, and the dog again lost his temper, with the effect of stopping the secretion of gastric fluid for the next fifteen minutes. A case of a girl is reported in whom the gastric secretion long outlasted the period of eating, although owing to esophageal and gastric fistulæ no food entered the stomach. It has been recently shown that psychic disturbances similar to those just shown will inhibit the secretion of the pancreatic juice and the flow of the bile.

Cannon asserts, just as there are psychic secretions, so there is probably a "psychic tone," or "psychic contraction" of the gastrointestinal muscles as a result of taking food. For if the vagus is cut *just before taking food* the usual gastric wall contractions do not occur, but if this nerve is cut *after* food has been eaten with a relish, the contractions which have already started continue without cessation. As both of the above operations had been done under anesthesia, the incidence of pain could not have influenced the results. In the absence of hunger, which in itself provides a contracted stomach, the pleasurable taking of food may therefore be a primary condition for the appearance of natural contractions of the gastrointestinal canal.

Pain produces the same change as the emotions of which we have just spoken, both in the external parts of the body and in the internal secretions. Wertheimer proved many years ago that stimulation of a sensory nerve in an anesthetized animal—such stimulation as in a conscious animal would induce pain—quickly abolished the contractions of the stomach, and Netschaiev showed that excitation of the sensory fibers of the sciatic nerve for two or three minutes resulted in an inhibition of the secretion of gastric juice, which lasted for several hours.

Emotional conditions or feelings may produce opposite effects on the alimentary canal, some favorable to digestion and some inhibitory. These opposing conditions are expressed through nerves which are correspondingly opposed in their influence on the digestive organs. The cranial nerves are the agents for psychic secretion in the salivary glands, and cause also dilatation of the blood vessels of these glands.

Pawlow has shown also that when the vagi are severed psychic secretion is abolished. These nerves tend strongly toward bodily conservation by contracting the pupils against intense light and slowing the heart rate, which gives rest to the cardiac muscles. They also provide for the flow of saliva and of the gastric juice and by supplying the muscular tone needed for the contractions of the alimentary canal, they bring about and regulate digestion and absorption. They form one of our bodily balances to build up the reserves and fortify the organism against stress and privation.

One of the striking features of a disordered metabolism which seems to be the underlying condition in diabetes, cancer, and insanity, as well as in many other dyscrasiæ, is glycosuria. Folin and Dennis found glycosuria in 19 per cent. of 192 insane patients, most of whom suffered from some form of depression, apprehension, or excitement, and Arndt has reported the appearance and disappearance of glycosuria in his patients concomitantly with the appearance and disappearance of alcoholic delirium.

Bohm and Hoffman produced abundant glycosuria in about one-half of a number of cats bound to a board having a tube in the trachea and another in the urethra. So long as the glycosuria lasted, in three determinations, the sugar in the blood was slightly above normal, but returned to normal when the sugar disappeared from the urine. This form of glycosuria caused by binding animals securely in a fixed position was dubbed Fesselungs Diabetes, which cannot be justly called emotional glycosuria, although it was found to depend largely upon the state of excitement of the animal. In three of the cats so bound no glycosuria followed pain, cooling, or bandaging. They remained calm and passive, although bound in the holder for four consecutive hours, but when confined singly in cages, and barked at for a half hour by an energetic dog, they promptly developed the sugar in their urine.

Nine medical students submitted their urine to a test for sugar before and after a hard examination. Four of them had glycosuria at the second test, though none of them had it at the first one. The same procedure was adopted before and after an easy examination, and then only one of the students showed the glycosuria. Twelve out of the twenty-five football players in the Harvard University team had glycosuria after the most strenuous game of the year in 1913. Of those showing sugar five were substitutes and did not get into the game. None of the twenty-five had any sugar in their water on the day before the game. An excited spectator also showed glycosuria after the game, which had disappeared on the following day. From these and a number of similar cases it is

shown that men, cats, dogs, and rabbits have a temporary increase of sugar in the urine, and coincidentally, in the blood, from emotional excitement.

Since artificial stimulation of the splanchnic nerves produces glycosuria, and since major emotions such as rage and fright, are attended by nervous discharges along the splanchnic pathways, glycosuria would be expected as a concomitant of excitement. How much the stimulation of the adrenal glands may contribute to this result has been a matter of dispute. Cannon, after careful experimentation, convinced himself that removal of the adrenals inhibits glycosuria. It may be noted in passing that the liberation of sugar and adrenalin at the moment when great muscular exertion is about to be demanded of the body is a significant instance of biological adaptation.

The first, because the sugar is needed in the unusual effort. The second, because the adrenalin directly stimulates muscular action and clears away the fatigue products (metabolites) and so revives the drooping strength. This property of adrenalin will be spoken of again under the heading "second wind."

As the abdominal arteries and veins are under the control of the splanchnic nerves and, as intimated above, states of excitement are characterized by discharges of energy through these nerves, so in violent effort the diaphragm and the muscles of the belly-wall are voluntarily and antagonistically contracted, in order to stiffen the trunk as a support for the arms and the abdominal muscles, which result forces the blood out of the belly and does not permit its return until the parts are relaxed. It is well known that blood pressure may suddenly rise from 110 mm. to 180 mm. during extreme physical effort, which shows that a larger quantity of blood than usual goes to the heart for distribution to the skeletal muscles and this blood as just pointed out is temporarily taken away from the great vessels of the abdomen.

Oliver and Schaefer were able to show by actual measurement that the viscera of the splanchnic area, the spleen, kidneys, and intestines suffer a considerable decrease of volume, when adrenalin is administered, whereas the limbs show a corresponding increase in size and the relative degrees of sympathetic innervations may be judged by the action of the adrenalin in a given case. In other words, at times of pain or excitement, sympathetic nerve discharges, probably aided by the adrenal secretion, simultaneously liberated, will drive the blood out of the vegetative organs of the interior of the body into the skeletal muscles.

There is one very important exception to the statement that adrenalin will empty the visceral vessels of their blood. As has been pointed out, adrenalin has a vasodilator and not a vasoconstrictor action on the cardiac arteries. It is also well known that this powerful agent has little or no effect upon the cerebral and pulmonary bloodvessels. Thus we see that the blood supply of the "tripod of life" is not diminished in physical stress; on the contrary, the heart actually has more blood to send to the muscles, borrowed from the viscera, which do not need it at the time, while the brain and lungs have an undiminished supply. This is an exceedingly significant and impressive biological fact.

It has been found that when adrenalin is set free in the circulation the blood will clot more rapidly. This is, of course, another safeguard developed by nature in animals as a preservative in times of conflict and injury. After long study of this question Cannon concludes that the property of causing a more rapid clotting of the blood does not reside in the adrenalin itself but in the liver, and that the action of the adrenalin is to force the liver to set free this blood-clotting agent in the bloodstream in greater abundance, in times of stress, than in ordinary conditions. This substance, whatever it may be, is continuously destroyed in the body and apparently as rapidly renewed in the liver. The above statement has not been yet conclusively proved to be correct, but there seems little doubt that the facts are as stated.

Another interesting phase of animal life gradually perfected through a long period of evolution is that correlated action of various functions which we know as reflexes. The most characteristic feature of reflexes is their "purposive" nature, or their utility either in preserving the integrity of the organism, or in safeguarding it from injury. When, therefore, we have discovered that among the automatic reflexes accompanying pain, fear, and rage, are the increased discharge of adrenalin and of sugar into the blood, we are led to inquire into the utility of this phenomenon.

To be of the most value to the economy in times of stress these reactions must be prompt. This we find to be the case. If the splanchnic nerve be stimulated below the diaphragm, a responsive secretion of adrenalin will occur in 16 seconds, and, within a few minutes after the stimulation of the same nerve, the sugar content of the blood is increased between 10 and 30 per cent. This discovery of the periodic increase of the blood's sugar content and its variation with the bodily demands is another recent physiological triumph. The importance of sugar as a readily assimilable agent in the promotion of muscular activity has been long known. But that it is supplied by the bloodstream to the laboring muscles in quantities suited to the demand, and the *modus operandi* of the procedure have only recently been determined. Here is another most significant biological balance. Fear and anger are both capable of stimulating the splanchnic nerves, hence they call forth promptly the secretions which enable the body to prepare itself for combat or flight.

As a further proof, of the consumption of sugar as glycogen in muscular activity, Cannon cites the fact that the carbon-dioxide output during severe exertion may exceed by twenty fold the output during rest. The storage of glycogen in muscle and the disappearance of this deposit from the muscles after great exertion, are well known. This same phenomenon is also observed in muscles that have been over stimulated by strychnine. Hence we may note, in passing, that strychnine is contraindicated in shock. The lessened capacity for work of muscles deprived of their stored-up glycogen is well known, as is the simple chemical reaction between sugar and lactic acid which is observed after repeatd muscular contractions. All these phenomena show that carbohydrate material (glycogen and sugar) is the elective source of energy for muscular contraction.

We cannot develop this aspect of our subject as fully as we would like, as this paper is already assuming formidable proportions. Let us, however, for a moment take up another fruitful aspect of the body reflexes. Asphyxia, whether due to ex-

ternal or internal agencies, like pain and excitement, not only liberates adrenalin, but, as might be inferred from this property, also mobilizes sugar. This accords with the observations of McLeod who says that the increased liberation of glycogen from the liver is produced by muscular exertion. Here again, we observe a purposive reflex as possibly associated with increased carbon dioxide in the blood. Zuntz also asserts that the asphyxia of great physical exertion may call out the blood sugar to such a degree that, in spite of its increased use in the active muscles, glycosuria may ensue. The evidence already given that adrenalin relaxes the smooth muscles in the bronchioles, taken with the fact that it is freely liberated in asphyxia, shows that, by means of this agent, relief is automatically provided for in the body.

Thus, the well-known phenomenon of "second wind" is explained, by which almost miraculous relief and increase of efficiency are afforded to a distressed and nearly asphyxiated person. In other words, the asphyxia has set in motion the mechanism by which it has cured itself. So, in the establishment of the "second wind," in a struggling man, we note the same group of bodily changes leading to greater bodily efficiency that we have observed in pain and excitement.

To recapitulate, there are increase of blood sugar, increased secretion of adrenalin, altered circulation (already dwelt upon) by which the heart and through it the skeletal muscles, get more blood and the abdominal viscera less, while the supply to the lungs and brain remains stationary. Add to these the more rapid clotting of the blood as an effect of increased output of adrenalin, and the phenomenon of relieving fatigue following the addition of adrenalin to the bloodstream, and the increasing dynamic power of the muscular fiber due to this same agent, and we have a similar series of protective bodily processes that we have observed to occur after the play of the strong emotions, fear, anger, and pain.

Evolution has produced in the human body a marvelously balanced machine, which fortunately we are at last beginning to comprehend. When William James, the great psychologist, speaks of "Reservoirs of Power" he uses the term figuratively, yet he is mentioning facts and alluding to entities that every human and animal body is supplied with. From our present knowledge we are led to regard the adrenal glands as the balancing governors of the bodily machine, particularly in all times of stress and strain.

We have had an inkling of the great hemostatic power of adrenalin for a long time but we did not realize, and probably do not yet appreciate, its wonderful value as a recuperative and regulating agent. That it prevents fatigue and overcomes nervous and muscular exhaustion, in a variety of ways, Cannon and others have beautifully demonstrated. They have pushed forward by their physiological researches the bounds of medical knowledge, and have started a train of inquiry which promises results of the utmost value.

Pyloroplasty, the Operation of Choice. — It is quite evident that the immediate as well as the final results from 100 gastroenterostomy operations and from an equal number of pyloroplasties are clearly in favor of pyloroplasty in the experience of Finney. The only indication for gastroenterostomy is the impossibility of pyloroplasty because of adhesions or thickening.—*American Journal of the Medical Sciences.*

WOMEN IN THE MEDICAL PROFESSION.

By MAUDE GLASGOW, M.D.,

NEW YORK.

IN ancient Egypt, about 11,000 years before Christ, women were engaged in the practice of medicine, which was at that time associated with the priesthood, and women were eligible to all positions in the priesthood, even the highest, and on exactly the same terms as men. As we might expect from the large number of physicians of the feminine gender, the infant mortality was very low. Egypt, the cradle of art, of science, and of civilization, the country from which Moses obtained his sanitary knowledge, was a country which owed its scientific knowledge perhaps quite as much to woman as to man. Queen, afterwards the goddess, Isis, was called the mother of medicine because she introduced the science to her country. Herodotus speaks of ancient Egypt as the healthiest of countries.

The Iliad and the Odyssee refer to the wonderful skill of the female leeches, praising the deft fingers which drew the barb from the flesh, dressed the wounds and alleviated by soothing potions the sufferings of the wounded warriors. The name of one of these women was Polydamna, which means subduer of diseases. Many Greek women, the Roman writer Hyginus informs us, devoted themselves to the diseases of women, the profession being legalized for them after the male physicians had endeavored to prevent them practising at all; but it was discovered that sick women were dying rather than consult men, and although the male physicians had succeeded in having Agnodice condemned to death for practising on her own sex, hers was made a test case through the opposition of the women citizens to the cruel decree. Many Greek women won distinction in medicine, Hippocrates, Galen, and Pliny making frequent reference to their work and their prescriptions. Origenia, Aspasia, and Cleopatra won special distinction for themselves in the field of medicine. Aspasia (not the wife of Pericles) first used and taught podalic version, as pointed out by Hergott, in those cases of cephalic presentations where the oncoming head cannot advance, and her method was used for centuries, then lost, to be revived in modern times. Metradora wrote a book on diseases of women, and her reputation was so great—so widely acknowledged—that a statue was erected in her honor at Flos, in Asia Minor, and a manuscript of her work is still preserved in Florence. Latin writers make frequent mention of medica, in their writings, and epigraphic monuments, not only in Italy and Greece, but also in France and Spain, are incontestable proof of the successful practice of women in the field of medicine, as well as that of obstetrical art. Victoria, Leopardia, and Theodosia, are the names of women who practised in Rome so successfully that their names are still preserved nearly twenty centuries after their death. Many women physicians are found among the early Christian martyrs.

Throughout the world women have taken the lead in founding hospitals, as well as in hospital reform. The idea of the hospital originated with Fabiola, who built the first hospital at Ostia, on the Tiber, then the port of Rome. This innovation excited a great deal of comment from contemporaries. In the fifth century Helena erected hospitals on the routes between Rome and Con-

stantinople, so that the suffering and wounded soldiers might receive the care and attention they needed; and the humane Isabella of Spain was the first to erect hospital camps on the battlefield. During the war with the Moors she had these tents furnished at her own charge, with medicines, appliances, and attendants. The camps were known as the "Queen's Hospitals," and were the forerunners of the army hospitals of civilized nations. We all recall that it was Florence Nightingale who cut through the swathes of red tape when wounded soldiers were dying by thousands through official bungling, how she brought comfort and care and life to dying men when the brains of her male compeers had "given signs of inanition."

It would be invidious to pass over our own Clara Barton, who founded the American Red Cross, and Dorothea Dix, who brought reform to our hospitals for the insane; Elizabeth Fry's work in prison reform needs no comment. Dr. Elizabeth Blackwell founded in 1861 the organization which developed into the Sanitary Commission, and raised $92,000 for sick and wounded soldiers. Dr. Blackwell voluntarily resigned from the organization she had founded because of the professional jealousy displayed by the male physicians with whom she was necessarily brought in contact, and she did not wish sex prejudice to obstruct the great work she had begun.

During medieval times many women became famous because of their medical and surgical skill. Of these perhaps the most remarkable was Hildegarde (born 1108), of Bingen on the Rhine. This lady wrote on many branches of science, and her writings are considered the most important of the kind written during the middle ages prior to the time of Albertus Magnus. Hildegarde wrote books on materia medica, pathology, physiology, and therapeutics. In her work, "Liber Simplicis Medicinæ," she shows her knowledge of science to be far in advance of her age, and in "Liber Compositæ Medicinæ," and another work consisting of nine volumes, she shows a medical knowledge as remarkable as it was profound. Several editions of her last work were printed in the early part of the sixteenth century. The late Rudolph Virchow declares this work curiously complete in spite of its age. One of Hildegarde's books has been published recently by Teubner of Leipsic, and attention has been directed to the fact that the author was acquainted with many subjects of which the male doctors of the middle ages were ignorant. Hildegarde was an abbess, and such medical knowledge as hers explains why convents were centers of healing, where reigned, not magic, but scientific knowledge. The hospitals connected with the convents were greatly superior to those erected later in the seventeenth, eighteenth and nineteenth centuries. The latter, instead of being centers of life, were often breeding places of death. They were devoid of light and sunshine, while the convent hospitals presided over by women possessed an abundance of good water, light, and air, and their records put to shame the boasted progress which was actually retrogression. The mortality of State hospitals from the seventeenth to the middle of the nineteenth centuries was often as high as 50 and 60 per cent., and as it was women who had originated hospitals and carried them to a high state of proficiency, so it was women who did so much to effect their reformation. It was Mme. Necker and Florence Nightingale, the superiors of nursing sisterhoods, and other women who relieved the distressing hospital conditions which had developed under male administration. What women are really capable of has been shown in one little spot of our world. There is at least one place where they have had equal opportunity, equal encouragement, and equal emolument. In such a place it is perfectly fair and just and right to make comparisons between the sexes. At Salerno on the Gulf of that name was the mother of medical schools, a part of the famous university. Salerno was about 600 years ahead of most of our institutions of learning. Here men ond women met on equal terms. To attain a medical degree in this school it was necessary to take a preliminary course of three years, followed by a five years' course in medicine, and completed with one year's work with a skilled physician. What was the result? Never in the history of the world was there such a galaxy of learned, able, and famous women. Many filled chairs in the university. And of these women was Trotula, author of a book on the diseases of women, written in the eleventh century, and published several times after the invention of printing. She was the first to describe the operation of perineorrhaphy, and advocated its performance as soon as the laceration occurred. It may be remarked that nine centuries later the neglect of this advice has caused untold suffering and disability. Contemporary professors of medicine quoted freely from the writings of women. One of the women graduates was licensed to follow her profession by no less a person than King Ladislaus of Poland. Some of the other famous women were Abella, Rebecca de Guarna, Mercuriade, and Francesca. The names of these women have survived about 1,000 years.

The school at Salerno was considered the fount of medical authority all over Europe, and questions were referred to it as late as the eighteenth century.

In 1292 there were eight women doctors in Paris, as well as those in other parts of France. Some were surgeons, and were called cyurgicæ. But the old spirit of greed and intolerance was as active in Paris in the thirteenth century as it was in ancient Greece, when Agnodice was condemned to death for practising medicine on her own sex. In 1220, while the medical women of Salerno were covering themselves with never-withering laurels, the Faculty of Medicine in Paris had succeeded in obtaining an edict prohibiting anyone but themselves from practising medicine. One of their first victims was Jacobe Felicie, a medical woman who had achieved remarkable reputation in caring for the diseases peculiar to her sex. Her skill, her humanity, her respectability was undeniable. She was haled to court, where witnesses expressed their deepest gratitude to her and their admiration for her work; yet she was condemned to pay an enormous fine, and her sex was prohibited from practising their profession. According to the faculty the crime of this woman consisted in putting "her sickle into the harvest of others." It mattered not that women refused to consult men with regard to their intimate ailments until it was too late to help them. The greed of wealth and power was uppermost in their minds, so vested rights crushed ruthlessly for gain all gratitude and womanly modesty, and women doctors received a crushing blow from which they had not recovered at the end of many centuries. "Isabella of Castile was not the first of the long list of victims who, for lack of a doctor of their own

sex have been sacrificed through womanly modesty, and more's the pity, she will not be the last."

In Italy, in the eighteenth century, Anna Morandi Mazzelini fashioned those wonderful wax models which are still the pride of the anatomical museum of Bologna.

In England there was an ecclesiastical law dating from the time of Edgar permitting women to practise medicine as well as men. This law was abolished in the time of Henry V, to be reenacted in the time of Henry VIII. This change was brought about because the grasping, selfish spirit of the male physicians was proving hurtful to society. In the words of the law, "The Companie and Fellowship of Surgeons of London myinding only their own lucres and nothing the profit or ease of the diseased or patient have sued, vexed, and troubled the aforesaid honest psones" who were henceforth to be allowed "to practyse without sute, vexation, penalty, or loss of their goods." Wherever men had power to prevent it, women were denied the privilege of such medical education as the times afforded, as well as legal right to practise their chosen profession, to hold lawful title or receive honor or emolument such as the men demanded for themselves. But there is always rebellion against injustice and unnatural laws obtained by force or fraud, so all over the continent of Europe, from the earliest times, women acquired a knowledge of the human body, of science, of natural laws and of the medicinal properties of herbs. They learned how to make decoctions, and extracts, and essences from the plants they had sorted and gathered, and the combined knowledge they had acquired they used to soothe and heal the human body. This medical knowledge descended from mother to daughter through centuries, with additions from age to age, and the skill of these "Wise Women" was widely acknowledged.

Paracelsus states with regard to his famous writings that they were but the compilation of knowledge obtained from the "Wise Women." It may be noticed that it is the women and not the men of primitive races, as a rule, who are learned in the healing properties of plants. The wise women were credited with unusual psychic knowledge and with ability in making scientific discoveries. Indeed, the unusual skill they had acquired was so remarkable that the ignorant and credulous populace thought this wonderful power must have been acquired in some uncanny way, perhaps from the devil himself, and when the persecution of witches began, even those who had been healed by the kindly offices of the wise women were ready to testify against them. It has been said that the so-called witches were the scientists of the age, though like Severus, and other scientific men, they paid for their skill and ability with their lives. Michelet makes the following statement in "La Sorcière: "The only physician of the people for a thousand years was the witch. The emperors, kings, popes, and barons had indeed the doctors of Salerno, then Moors and Jews, but the bulk of the people in every state, it might as well be called the world, consulted none but the 'wise women'." The term witch, is derived from *wekken*, to know, or to prophesy, the corresponding word in the Slavonic and German languages having the same signification. In the fourteenth century the church decreed that any woman who healed without having duly studied was a witch, and should suffer death; yet in 1517, at Basle, Paracelsus threw all his medical works into the fire, saying that he possessed no knowledge save that obtained from the witches.

The knowledge of drugs which these women possessed can be traced back between five hundred and a thousand years, and it is of great interest at the present time to note that they used anesthesia to mitigate the pains of childbirth. The drugs mainly used for this purpose were obtained from the Solanaceæ family, which includes belladonna and the famous scopolamine; the latter drug has recently been introduced into the United States largely through the instrumentality of two laywomen who have been roundly berated for their pains. The use of scopolamine therefore is but a revival of a method discovered and used by the wise women hundreds of years ago. Michelet says: "I make no doubt that this (Paracelsus') admirable work on the diseases of women . . . so large, so deep, so tender, came forth from his special experience of those women to whom others went for aid, the witches, who acted as midwives; for never in those days was a male physician admitted to the women. . . . In childbirth a motherly hand instilled the gentle poison, casting the mother herself into a sleep, and soothing the infant's passage after the manner of modern chloroform, into the world." The witch, it is said, "was the profoundest thinker and the most advanced scientist of those ages," so that the attack waged against the wise women was an assault upon wisdom and science, the usual thing in the dark ages. Accusations of witchcraft were common against the wise women. "Male physicians not skillful enough to cure disease would deliberately swear there could be but one reason for their failure—the use of witchcraft against them." The persecuted women were compelled to abandon their long-practised profession of medicine and surgery. They suffered torture and death because of their knowledge and skill, and unable to longer withstand the persecution, left the field for a time to their male competitors.

The Thracians named their State "Thracia," in honor of a noted woman physician who discovered the use of aconite, still a much used and valuable drug; aspidium, a drug we regard as indispensable in the treatment of tapeworm, was discovered by Mme. Mouffler, and was purchased from her in 1775 by Louis XVI for the sum of 1,800 francs. Edward Jenner obtained from an English milkmaid the information which he afterward used in vaccinating against smallpox, and Lady Mary Wortley Montagu introduced the practice of inoculation with smallpox virus as a prophylactic against the disease into western Europe. Our valuable specific against malaria—quinine—is obtained from cinchona bark, the use of which in Europe was made general through its introduction by the countess of Chinchon, vicereine of Peru. Lady Chinchon was cured of malaria herself in 1638 while residing in Lima. On her return to Spain she made the drug widely known. The name of the countess is now borne by eight score species of the trees which constitute the genus cinchona.

Mme. La Chapelle and M. Chaussure revived the use of belladonna during parturition, thus acknowledging the previous scientific skill of the wise women who were burned to death because of the envy and malice excited by their ability.

Louise Bourgeois was a celebrated midwife who was educated in the Paré school for midwives. It was Ambrose Paré who revived the practice of

podalic version discovered by the Greek woman physician, Aspasia. Louise officiated at the birth of many royal children, and has left interesting writings behind her. At this period men were not admitted to the lying-in room. Mme. Boivin practised at the Paris Maternité. She published a work on hydatid mole, after which she received an honorary degree—that of M.D.—from Marburg University.

Many midwives made themselves famous, and among these were Regina von Siebold, Carlotta, her daughter, and Theresa Frei. The first had the honorary degree of doctor of obstetrics conferred upon her by the University of Giessen in 1819. (Queen Victoria was one of her patients.) Her daughter also won an honorary degree in obstetrics from the same university, as well as Frau Frei. This university honored itself in honoring these self-made women, for these women owed nothing to college or school, but everything to their own ability. The first woman to win a doctorate in Germany was Dorothea Erxleben, but she received this as a special favor from Frederick the Great. Marie Bovin entered upon her career after the French Revolution. She introduced a number of improvements in the lying-in hospitals, and trained a large number of women in midwifery. Her writings on obstetrics secured for her a reputation which was unsurpassed by any. Her "Pratique des Accouchements," in three volumes, is based on an experience gained in 50,000 labors. This book was long regarded as a standard work, and exerted a remarkable influence in scientific and medical circles. Another of her books passed through several editions and was translated into several languages. These clever women were not admitted to classrooms or laboratories. They owed nothing to colleges or governments, and were obliged to overcome countless obstacles placed in their way.

Bologna afterward became a great center of science and learning, and here again was witnessed a blossoming of female genius. There is an extended list of the names of women in the honor list of Bologna, names famous throughout Europe, "the rivals, sometimes the superiors, of the ablest men among their distinguished colleagues."

Napoleon established a chair of obstetrics for Maria dalle Donne in her alma mater. She had been a poor peasant girl. The position thus created was filled until the lady's death in 1842.

Mme. Curie's discovery of radium, a substance of such scientific promise in the medical world, and the attitude of the medical members of the French Academy toward this genius when the question of admitting her to its membership came up, show the persistent and consistent refusal of men to recognize or reward unusual skill or ability when the possessor is a woman.

When women re-entered the field of medicine they found themselves in the country of an enemy. Men occupied exclusively the field which had been woman's when the race was in its cradle, and for thousands of years afterward. The opposition to be faced was as bitter as it was unceasing and unscrupulous. The doors of medical schools were closed in the woman's face. Medical men who dared to meet her in consultation were promptly disciplined. She was refused membership in medical societies and driven out of operating theaters where the patient under the knife was a woman. Hospitals where her sex received medical and surgical aid refused her admittance, while it welcomed women as nurses. Misrepresentation, intimidation, calumny, and abuse became familiar, as they are to all invaders of vested rights and to all those who would enter the enclosure of the trades unionist. There were notable exceptions, to be sure, but leaders in the profession were leaders in the tactics to which reference has been made.

Elizabeth Blackwell's entrance into the field of medicine in the middle of the last century was a distinctly epoch-making event. The initiative, energy, and intellectual power necessary to the successful pursuit of her object were phenomenal, and if instead of wasting her precious ability in fighting for a foothold, the door of medical opportunity had been open to her as it was to the most mediocre men, humanity would have been benefited. Yet, handicapped as she was, our first medical woman has left a name behind which will be remembered as long as the English language is spoken. Medical women are still handicapped, and so long as these handicaps are allowed to remain society is the loser. The public should insist that medical men and medical women shall enjoy precisely the same advantages, not only in college, but also in hospital and dispensary, for while women are denied the advantage of appointment on the visiting staffs of our hospitals, it is absurd to expect that they can rival the work of those who hold such positions. The critics who say "we have no famous women doctors or women surgeons" must be ignorant of the way skill in diagnosis and brilliancy of technique are acquired and developed. If the persons making such statements are not ignorant they are disingenuous.

Women have been so long in tutelage that perhaps it should not be considered strange that even the college woman who has studied seven or eight years should still be considered unfit to choose without assistance the branch of medicine for which she is best suited. But it is surely a distinctly unfriendly act to try to discourage her at the outset of her career, no matter how wise or altruistic the adviser may be. Nature's laws, however, have a way of asserting themselves to the very decided discomfiture of some biologists and scientists who have added a few laws of their own making to those of nature's creation. What women may achieve in medicine can never be known until she enjoys the same opportunities and the same encouragement as her brother. And what branch of medicine she is best fitted for will not be known, either, if she is pushed into this or that niche and advised with forcible kindness to stay there. Woman's sympathy and conscientiousness specially fit her to take up and pursue a profession which requires much sympathy, and which confers a great responsibility upon those who follow it. Less than half a century ago Britain tried by unjust and even brutal methods to keep women out of the field of medicine. To-day a joint appeal has been issued by the anti-suffragist Lord Curzon, Mr. Asquith, and Mr. Balfour for the training of medical women, so increasingly large numbers of women are studying medicine, and the Free Royal Hospital school is doubling its facilities to meet the demand. The Endell Street Hospital in London is entirely in the charge of women physicians, who have equal army rank with male doctors in other hospitals. They wear khaki uniforms, with the insignia of their rank. Contrary to expectation, we have a number of expert women surgeons. In the obstetrical field they have held the fort for thousands of years, and

he would be rash indeed who would say that here they should yield the right of way to man. England has two women surgeons in the field at present, Germany one, and Russia three, France has one woman surgeon to her credit on the field of battle.

That women desire physicians of their own sex is well known, when they know it is possible to have them, for many men and women even in our own city have never met a woman physician. Notice the dispensaries crowded with women patients where the attending physicians are exclusively women, though other more pretentious and impressive dispensaries abound.

Medical women are not begging for favors, but they desire a square deal—a fair field and no favor. Shall they ask in vain?

FERMENTED MILK AND WHEY IN INFANT FEEDING.

By ALBERT E. MUCKLOW, M.D.,

BROOKLYN, N. Y.

In a previous article[1] the rationale of feeding infants with fermented milk was considered in detail. Since then the smallest amount of water compatible with proper percentages has been used in the formulas, whey having been substituted for it as much as possible. This change has been made in order to take advantage of the saline constituents and the "vitamins"[2,3] of whey.

In the past, the objection to whey in milk modifications has been the necessity of heating it, before adding it to the milk, to a temperature sufficient to destroy the rennet without coagulating the whey proteins.[4] With fermented milk and whey mixtures no heating of the whey is required as the flocculent curds of coagulated casein in the fermented milk are unaffected by rennet. The whey can be conveniently prepared from the skimmed milk remaining in the bottle from which the top milk for the formula has been removed.

A series of analyses were made for me by Dr. Harris Moak of the Kings County Milk Commission to determine the composition of whey made from hand-skimmed milk. Dr. Moak removed the cream with a dipper from bottles of milk containing, respectively, 4 per cent., 4.40 per cent., 5.20 per cent., and 5.60 per cent. of fat. Whey was made from the resulting skimmed milk in the manner described in a subsequent paragraph. It was observed that a yield of 6 ounces of whey was obtained from each 8 ounces of skimmed milk employed.

As seen by the accompanying table, very little difference exists in the composition of whey made from skimmed milks originally of different degrees of richness. Hence, for all practical purposes we may take the average of these findings and consider the composition of whey made from hand-skimmed milk to be in all instances as follows:

Whey
(Made from Hand-Skimmed Milk)

Fat	0 03 per cent.
Proteins	0 85 per cent.
Sugar	5 18 per cent.
Ash	0 33 per cent.

The methods employed in determining the fat, proteins, sugar, and totals solids were the same as those used in the former analyses of top milks.[1]

The bacterial count of the milk is lowered in the process of making the whey as shown by two samples of skimmed milk with a bacterial count of 1,950 per c.c. and 3,150 per c.c., respectively. Whey made from these showed a count of only 1,090 per c.c. and 930 per c.c., respectively. This probably is due to the proteolytic effect of the pepsin.

Milk sugar has replaced the malt sugar recommended in the previous article,[1] the best brands of the former having been found, upon analyses, to be very pure products. One ounce by volume of most milk sugars represents approximately one-half ounce by weight and has been so considered in calculating the accompanying formulas. However, as this does not hold true for all brands, the weight of an ounce dipperful of the one selected should be ascertained.

The addition of bicarbonate of soda to the fermented milk to decrease the acidity and thereby make it more palatable, has been discontinued. The milk is sufficiently palatable without it and the greater acidity is desirable, being more antagonistic to pathogenic bacteria. The germicidal effect of lactic acid in milk has recently been emphasized by Heinemann[6] of the Department of Bacteriology and Hygiene at the University of Chicago.

The ideal temperature for fermenting the milk has been found to be 98 deg. Fahr., in which temperature a sufficient amount of lactic acid to destroy harmful bacteria is most speedily produced.

The armamentarium has been increased, consisting in its entirety of the following: the semi-circular metal compartment described in the previous article,[1] lamp, thermometer, Kreamer No. 8 wash boiler in which to sterilize the utensils, large-sized enameled skimmer to remove small articles from the boiler after sterilization, Chapin one-ounce cream dipper, fine-meshed strainer, six one-quart Lightning preserve jars with rubber washers, two one-pint glass tumblers, two three and a half quart enameled pitchers, enameled pot to be used for the water bath in making the whey, a long-handled fork, eight one-foot square pieces of the finest-meshed cheese cloth, two enameled pans, one to be

Whey Made from Hand-Skimmed Milk.

used as a sterile receptacle for the small utensils while preparing the mixtures and the other to be kept filled with boiling water to quickly sterilize any article that may become contaminated while in use, and a No. 50½ Chattilons straight spring balance scales graduated in quarter pounds and weighing up to thirty pounds.

In estimating the depth of the cream layers, measurements as small as quarter dipperfuls have been found practical. Hence, the following has been adopted to secure greater accuracy in judging the richness of a given bottle full of milk:

4.00 Per Cent. Fat Milk	4.40 to 4.80 Per Cent. Fat Milk	5.20 to 5.60 Per Cent. Fat Milk
Cream layer, less than $5\frac{1}{2}$ dipperfuls	Cream layer, $5\frac{1}{2}$ to $6\frac{1}{4}$ dipperfuls	Cream layer, more than $6\frac{1}{4}$ dipperfuls

In preparing a formula in which only top milk is used, the richness of a given bottle full of milk may be determined as follows:

Dip off the top 4 dipperfuls into a pint tumbler. Dip off the 5th dipperful into a second pint tumbler. Dip off the 6th dipperful into a one-half pint tumbler to avoid confusion. Dip off and discard the 7th dipperful. Note the amount of cream removed. Depending upon the amount of top milk required, use the 4 dipperfuls in the first tumbler; the 4 dipperfuls in the first tumbler mixed with the 1 dipperful in the second tumbler; or, the 4 dipperfuls in the first tumbler mixed with the 1 dipperful in the second tumbler and the 1 dipperful in the third tumbler.

In preparing a formula in which whole milk is used, it will be more convenient to adopt the following procedure:

Dip off the cream from the bottle from which the whole milk is to be taken and note the number of dipperfuls removed. Mix the cream thus dipped off with the rest of the contents of the bottle from which it was taken.

The majority of healthy infants will require at the different ages the percentages of proteins given in the accompanying formulas. However, we must individualize. A child progressing favorably with a given formula may continue upon it longer than indicated in the schedule. Conversely, a failure to steadily gain should prompt us to advance to a stronger formula earlier than there directed. During the first six months a weekly gain in weight of eight ounces together with normal stools (two or three yellow, mushy, homogeneous stools daily) is desired.

Infants feeble from prematurity, sickness, or previous faulty feeding should, on account of the low ebb of their assimilative functions, be given for a time mixtures with a lower protein content than that indicated by their age, the subsequent use of richer ones being permitted with the return of full absorptive powers, as will be shown by the continuance of normal stools under such advance.

Feeble infants should also, because of their gastric intolerance, be given for a short time a low percentage of fat, the subsequent advance to the highest percentage being as rapid as possible on account of the value of the butter fat *per se* and the "vitamins"[2,3] associated with it.

The formulas, the calculations by which they are obtained, and the method of their preparation are shown herewith.

(MIDDLING INFANTS)
AGE: 6 TO 8 MONTHS — 4.40 TO 4.80 % FAT MILK

	% Fat	% Prot.	% Sug.	% Ash	Parts	% Fat	% Prot.	% Sug.	% Ash
Top, 5 oz. after fermenting	23.90	2.71	3.39	0.55	=1	23 90	2.71	3.39	0.55
Whole milk, 3 oz. after fermenting	4.60	3.20	4.11	0 70	= ⅗	2 76	1 92	2 46	0.42
Whey, 15 oz	0.03	0.85	5.18	0.33	=3	0.09	2.55	15.54	0.99
Water, 1 oz					= ⅕				
					4⅘)	26.75	7.18	21.39	1.96
The above 24 oz. will thus contain						5.57	1.49	4 45	0.40
6.50%−4.45%=2.05%=percentage of additional sugar needed.									
24 oz.×2.05%=approximately ½ oz.=amt. of sugar required by weight.									
1 oz. of milk sugar by volume=approximately ½ oz. by weight. Therefore replacing ½ oz. of water with 1 level dipperful (½ oz. by weight) of milk sugar adds approximately 2.05%.								2.05	
Composition of complete mixture						5 57	1.49	6 50	0.40

(MIDDLING INFANTS)
AGE: 6 TO 8 MONTHS — 4.40 TO 4.80% FAT MILK

Dip off into a pitcher the cream from a quart bottle full of milk that has not been disturbed. Note the number of these dipperfuls in order to determine the richness of the milk. Pour the rest of the contents of the bottle into the same pitcher. Pour the entire amount back into the bottle. Again pour the contents of the bottle into the pitcher and back into the bottle; that is, four pourings in all.

Dip off into the empty pitcher 3 dipperfuls of this mixed milk.

Skim off the top 5 dipperfuls from another quart bottle full of milk that has not been disturbed and add these to the above milk in the pitcher.

Add either the contents of a vial of the Bulgarian bacillus culture (add this every fourth day) or ½ teaspoonful of the preceding day's fermented milk.

Pour into a quart preserve jar. Seal it and stand without disturbing in 90 deg. to 100 deg. (best 98 deg.) F. for 24 hours.

Rub through a fine meshed strainer to make the flocculi small enough to pass readily through the hole in the nipple. Be sure to leave none on the strainer.

Excepting every fourth day take ½ teaspoonful of this and add it to the next milk to be fermented.

Add to the above fermented and strained milk 15 dipperfuls of whey, ½ dipperful of cold water, and 1 level dipperful of milk sugar.

Pour the completed mixture into two quart preserve jars. Seal them, immediately place in the ice chamber of a refrigerator next to ice and there keep them until needed. At feeding time shake well, pour out the required amount, then immediately reseal the jar, and replace it on ice. The amount poured out should, without delay, be warmed and fed.

The method by which the amount of the above mixture may be doubled is obvious. It may be increased by one-half as follows:

Dip off into a pitcher 4½ dipperfuls from a bottle full of mixed milk.

Skim off into a pint tumbler the top 5 dipperfuls from each of a second and a third quart bottle full of milk that has not been disturbed. Pour these 10 dipperfuls int o another pint tumbler, then back into the first tumbler, and repeat this procedure once; that is, four pourings in all. Add only 7½ dipperfuls of these to the above milk in the pitcher. Add 1½ times the above amounts of the other ingredients.

The following are imperative: Use Certified Milk.

The bottles of milk when received from the dealer and the jars containing the completed mixture, should immediately be placed in the ice chamber of a refrigerator either in the middle of the chamber with a cake of ice on either side of and in contact with them, or what is better but usually impractical, in a pail full of cracked ice. They should be kept in an upright position until needed.

Use a Chapin cream dipper, that has been accurately made to hold exactly one fluid ounce, to measure the milk, whey, water, and milk sugar. The first dipperful from a bottle full of milk should be removed with a teaspoon to avoid spilling.

A dozen vials of a culture of Bulgarian bacilli should be purchased as often as required direct from the laboratory of the manufacturer, immediately placed in the ice chamber of a refrigerator next to the ice and there kept until used.

The water used in the formulas should be cold and should have been either distilled or boiled for 5 minutes.

All utensils should be boiled for 5 minutes just before using them.

Feedings should be warmed by standing nursing bottle containing same in water not hotter than hand can bear, as too great a heat will toughen the curd.

Use a medium sized nipple with a single opening. Make opening the proper size by running through it the red hot point of a No. 7 sewing needle, the eye end of the needle being inserted into a cork to protect the fingers. After each nursing

turn the nipple inside out, scrub clean and place in borax water (one heaping teaspoonful of borax to a cupful of cold, boiled water).

The whey is prepared as follows:

Skim off from the bottle from which the top milk for the formula has been removed enough additional dipperfuls to make a total of 8 dipperfuls removed from that bottle.

Pour the resulting skimmed milk into a quart preserve jar.

Add 3 teaspoonfuls of a good essence of pepsin and stir.

Seal jar and stand in a kettle full of water as hot as hand can bear for one-half hour.

Break up the curd with a long-handled fork.

Strain through two thicknesses of the finest-meshed cheese cloth one-foot square placed on a strainer over a pitcher.

THE CONNELLAN-KING DIPLOCOCCI INFECTIONS OF THE THROAT, WITH ESPECIAL REFERENCE TO RHEUMATISM.*

BY JAMES JOSEPH KING, A.B., M.D.,
NEW YORK.
ATTENDING LARYNGOLOGIST, HOSPITAL FOR RUPTURED AND CRIPPLED; CHIEF-OF-CLINIC, EAR, NOSE AND THROAT, GOUVERNEUR HOSPITAL; ASSISTANT SURGEON IN OTOLOGY, NEW YORK EYE AND EAR INFIRMARY.

My attention was first directed to this diplococcus when it was found in the crypts of the tonsils of one of the physicians on the House Staff of the Hospital for Ruptured and Crippled about one year ago.

This patient was reported in my preliminary report on the Connellan-King diplococci, on March 24, 1915, before the Nose and Throat Section of the Academy of Medicine, and published in the *Laryngoscope*, April, 1915, as follows:

The first case was that of a physician who was first seen by me on November 27, 1914. He complained of sore throat and pains over the body. His temperature was 105.6° F. He was delirious and in a severe chill. Both tonsils had the appearance of a follicular tonsillitis. He was exceedingly toxic. Urine had albumin, hyaline, and granular casts. A gram negative diplococcus, which has since been called for lack of a better name—the Connellan-King diplococcus, was isolated from the deep crypts of each tonsil. Notwithstanding treatment, his nephritis, elevation of temperature, and toxic appearance persisted until he had received three injections of an autogenous vaccine.

This diplococcus was next found in the tonsils of another physician. He had a mild attack of tonsillitis in April, 1914. After a few days local treatment all symptoms disappeared. About three months later he developed acute arthritis of ankle and knee, and then acute endocarditis, myocarditis, and nephritis, with albumin, hyaline, and granular casts in the urine. He was confined to his bed for twelve weeks. In the fall of 1914 he was able to get around, but was not considered well.

In December, 1914, the Connellan-King diplococcus was isolated from the crypts of his tonsils. Three injections of autogenous vaccines cleared up all infection. In January, 1915, his tonsils were enucleated under local anesthesia at the New York Eye and Ear Infirmary. He made a good recovery from his operation, and has gained about forty pounds in weight since. He has had no arthritis nor rheumatic pains, and he says this is the first time in fifteen years that he has gone through a summer without them. His physicians report that his heart is normal, and he has been attending to his usual large practice in Atlantic City since he recovered from his tonsillectomy.

One other patient mentioned in the preliminary report had a similar history. She had a severe attack of tonsillitis in February, 1914. Three weeks later she developed a severe arthritis in ankles and knees. She was confined to her bed from Febru-

*Read before the New York County Medical Society, Oct. 25, 1915.

ary, 1914, to May, 1914. From May until August she was up and around in a wheel chair. She could walk with the aid of her nurse, a crutch and a walking stick; but the pain was persistent. She first consulted me in December, 1914, when the pain was still present, and she had to use the crutch and stick in walking.

The Connellan-King diplococcus was found in the crypts of her tonsils. Autogenous vaccines were prepared, and her physician in Kane, Pa., gave them to her under my direction. After seven injections the pain had ceased and she has no further use for her crutch and stick. A few days ago her brother informed me that she has had no further trouble, and had not been so well in years as she has been since her treatment with the autogenous vaccines.

In the preliminary note sixteen patients were reported. All were private patients except the one whose condition simulated a sarcoma of the tonsil. In all the Connellan-King diplococcus was isolated from the deep crypts of the tonsils. Two had such severe arthritis that they were confined to bed for periods of twelve and fourteen weeks respectively. Two had grave nephritis. All of the sixteen except two received autogenous vaccines. One of them who did not receive treatment with the autogenous vaccines has since been operated upon in Boston for calculus in bladder. Two of the series who did not receive treatment until many months after their first attack of tonsillitis suffered most severe complications. In one, the arthritis has been entirely relieved by the autogenous vaccines, and another has been so much benefited that she is able to get along without the use of her crutch after five injections. All of the fourteen who have received the autogenous vaccines are gratified with the great benefit received from their treatment. Some of the patients treated from the onset of their throat infections have had serious complications which were relieved by the autogenous vaccines, while two in whom the diplococcus was not isolated until many months after the initial tonsillitis were very ill for nearly a year.

Since the first report I have had sixty-two other patients in whose tonsils the Connellan-King diplococcus was found, making a total number of seventy-eight patients. The following representative types are from my private and hospital records:

Case I.—F. G., a boy of 11 years, admitted to Gouverneur Hospital May 20, 1915. Previous history not important, except that two years ago he was treated in Gouverneur Hospital for rheumatism for three weeks. From that time he has been well up to about May 10, 1915, when he developed pain and tenderness in left knee, left ankle, and right shoulder. The joints on admission were swollen, red and painful. Physical examination revealed nothing except a soft blowing systolic murmur of the heart at the apex and transmitted to the axilla, and the above-mentioned condition of the joints. Temperature on admission, 100.5° F.

On May 24 the mucosa of the pharynx and tonsils was of a distinctly purplish hue. The tonsils were moderate in size, and submerged behind the pillars. The Connellan-King diplococcus was isolated from them, and a vaccine made from the culture. Other laboratory findings, such as von Pirquet, blood count, blood culture, and urine examination negative, except for a small amount of indican in the urine.

He received ½ c.c. autogenous vaccine, representing 100,000,000 of the Connellan-King diplococci, on May 31, without any reaction except an increase in the pulse rate to 120-130. On each of the following dates, June 5, 11, 20, 24, he received by hypodermic injection 200,000,000 Connellan-King diplococci vaccine. No other treatment given.

Result: Gradual remission of temperature and pulse to normal. The pain, swelling and tenderness in joints entirely disappeared. His general condition greatly improved, gaining 10 or 15 pounds in weight. His heart murmur still persisted, but was improved. Discharged from the hospital in splendid condition, July 4, 1915.

Case II.—A. B., a strapping young fellow of 27 years, admitted to Gouverneur Hospital, March 23, 1915, for treatment of chronic articular rheumatism. He had been treated at home for the past seven months for rheumatic pains in his large joints, especially the ankles and knees, by a private physician without improvement. On admission to the hospital he had severe pains in all large joints, especially the knees and ankles, and they were swollen and tender on palpation. Temperature about 101° F. Physical examination otherwise negative.

Laboratory findings: Urine, negative; Wassermann negative; complement fixation negative for gonorrhea; blood cultures negative; leucocytes 13,600; polynuclears 65 per cent.; lymphocytes 35 per cent.; throat culture, Connellan-King diplococci.

Treatment: In addition to seven months' treatment at his home for rheumatism, he was treated in Gouverneur Hospital by the medical staff for fifty-three days without improvement. He was running a septic temperature during this time, and was kept in bed. His medication in the hospital consisted in the internal administration of sodium salicylate, sodium bicarbonates, and the external application of oil of wintergreen. He was baked every day for twenty days. The temperature of apparatus on entering was 170° F., and gradually increased up to 320° F. on leaving. He was kept in the apparatus for twenty minutes each day.

I was asked by the medical staff to investigate his throat condition on his fifty-third day in the hospital, and it was then that the little gram-negative diplococcus was found in his tonsils. All other treatments and medication were stopped, and the Connellan-King diplococcus autogenous vaccines were begun. His first injection of 200,000,000, on May 15, produced a marked reaction, with elevation of temperature to 102.6° F. A second injection of 250,000,000 was given him on May 19, with less reaction than the first. After the second treatment he was decidedly more comfortable, and his temperature gradually receded to normal. Two other injections of similar strength were given him at intervals of four days. He was discharged from the hospital, after a stay of eighty-five days, on June 16 as cured.

Case III.—Mrs. A. K. T., age 56 years, referred to me on July 24, 1915. She was markedly anemic, due to sepsis of the tonsils and Rigg's disease. The tonsils were large, the crypts filled with caseous material, and the color may be described as leathery—an unhealthy appearance. The Connellan-King diplococcus was isolated from the crypts, and treatment begun with the autogenous vaccines by hypodermic injection. Her blood examination on July 29 is given below, and I report this case merely to show the improvement in her blood picture after five injections of autogenous vaccines, which she received between July 29 and September 10.

Blood Examination.

July 29.		Sept. 10.
78	Hemoglobin	78
4,480,000	Red Cells	5,360,000
7,900	Leucocytes	9,800
	Differential 500 *Leucocytes.*	
34 per cent.	Polynuclear	64 per cent.
2.4 per cent.	Transitional	4.8 per cent.
57.4 per cent.	Lymphocytes, small	21.2 per cent.

Other elements about normal in each examination.

Her general appearance has improved, and I believe that the blood changes, increase in leucocytes, and the polynuclear count, indicate an increase in her resistance.

Case IV.—Miss E. S., age 26, referred to me July 15, 1915. Briefly stated her history is: An attack of tonsillitis five and a half years ago. One month later arthritis developed in feet and knees. It has been progressive in spite of almost constant treatment, including four or five trips each of one month's duration to Mount Clemens, Mich.

Examination: Joints of hands and knees very much swollen and deformed, and continual pains in them. Valvular disease present, with a distinct mitral regurgitation. Tonsils moderate in size, purplish hue. Culture from them revealed Connellan-King diplo-

coccus. She was treated with the vaccines with great improvement.

On September 8, 1915, I enucleated her tonsils at the New York Eye and Ear Infirmary. She made an uneventful recovery. Her joints are now almost normal in size and free from pains. Her heart murmur persists, but is softer in character, and I believe improved. Her color and general condition are greatly improved.

Case V.—T. N., male, age 11 years. Admitted to the Hospital for the Ruptured and Crippled, August 3, 1915. Family and personal history unimportant. Present illness: The knees are swollen, tender and painful. Three weeks previously he was struck by a wagon and fell upon his knees. Was treated by a private doctor at his home for rheumatism for three weeks. Upon admission to the hospital, temperature 100° F. Unable to walk or to straighten out his legs. Joints aspirated, and a straw colored fluid obtained. Culture made from this fluid was negative. Culture from tonsils showed Connellan-King diplococci and *Staphylococcus albus*. Up to this time he had received salicylate of sodium and sodium bicarbonate without improvement; that is, he had the ordinary rheumatic remedies for four weeks, including three weeks' treatment at home by a physician, and six days' treatment at the Hospital for Ruptured and Crippled, where he was kept in bed.

On August 8 he was given 100,000,000 Connellan-King diplococcus vaccine, and all other treatment stopped. On August 14 and 18 he received other injections of the vaccine. His pain and inflammation gradually subsided. Since that time improvement continued until he felt perfectly well. On September 2, his tonsils and adenoids were removed by Dr. O'Brien, the house surgeon, and on September 10 he was discharged as cured.

For the privilege of seeing the next case I am indebted to Dr. Austin, of Tuckahoe, and take this opportunity of expressing my thanks to him and to the staff of the Lawrence Hospital in Bronxville for the courtesy extended to me at the time.

Case VI.—C. S., aged 54, janitor, was admitted to the Bronxville Hospital, April 7, 1915. Present illness: About March 1 had a cold in head and mild attack of tonsillitis. March 14 had to quit work on account of pains in feet, ankles, hips, and hands. This attack confined him to his home for ten days. He then felt well enough to return to work. Two days later he had to be carried home again on account of a similar condition. From March 29 until admitted to the hospital he suffered with pains in almost all joints and along nerve tracts of the thigh. When admitted to the Lawrence Hospital on April 7, he complained of pains in all joints and along thighs.

Examination on admission: Temperature, 100.2° F.; pulse 84; respiration 22. Tonsils red with crypts filled with cheesy deposits. Pharynx a purplish hue, much darker than normal. Joints at fingers, wrists, knees, and ankles swollen, red, and painful. Arteries, lungs, and abdomen, negative. Soft systolic blowing murmur heard at apex, not transmitted to axilla but heard best midway between apex and ensiform cartilage. The diagnosis of subacute articular rheumatism with acute endocarditis was made.

Laboratory findings: Uurine negative; two blood cultures negative. Differential leucocyte count negative, except for 4 per cent. eosinophiles. Culture from tonsils presented Connellan-King diplococcus (about April 15).

Treatment: Usual treatment for rheumatism at his home for about two weeks before entering hospital. After entering hospital his treatment consisted in the internal administration of aspirin, salol, and sodium salicylate, codein for the relief of excruciating pains, and hot applications to the joints. This treatment was continued until April 23, when he received his first injection of autogenous vaccine. From this time on he received no medication except elixir iron, quinine and strychnine, cathartics as needed, and 1 c.c. (equal to 200,000,000 Connellan-King diplococci) of vaccine by hypodermic injection every fourth day until discharged.

Course of illness: From April 7 to April 23 his temperature was irregular, ranging from 98.2° to 102° F. Pulse ranged from 78 to 100, usually being from 84 to 90. He had numerous exacerbations of symptoms in spite of medication. His pains were so severe at times that he would scream out on movement of the affected parts. He was in such agony that he was unable to help himself and had to be fed. From April 20 to April 26 his condition was very bad from excruciating pains and exhaustion. He was frequently delirious, and seemed as though he might die at any time from exhaustion and toxemia.

On April 23 he was given 1 c.c. of Connellan-King diplococci vaccine by hypodermic, with no apparent result. On the third day after his first injection of the vaccine his temperature reached 102.8° F. The next day he received the second injection of vaccine, when his temperature was 100.6° F. It receded after this injection to 98.4° F., rising again the next day to 100.6° F. It rose next day to 99.6° F., and fluctuated between 98.4° F. and 99.4° F. for the next three days. On the day following the third injection he felt so much better that he was able to get out of bed, and was in a wheel chair in the sun parlor most of the day. On May 7, 13, 18, and 24 he received injections of the vaccine. His temperature and pulse rate rapidly became normal after the third injection. He gained in weight, his color and general condition were improved, and he was absolutely free from pain in all joints after three injections. The appearance of the joints became normal. After taking seven injections of the vaccine he felt so well and strong that he refused to stay longer in the hospital and went home in good condition. His heart murmur still persisted, but it is recorded on his chart as improved. He said on leaving the hospital that he never expected to feel as well as he did then.

Conclusions: 1. Every case of septic arthritis, commonly called rheumatism, is caused by a focus of infection somewhere in the body. It may be in the tonsils, ear, accessory sinuses, gastroenteric tract, genitourinary tract, or in the teeth.

2. The most frequent focus is found in the mouth; and the tonsils, due to their crypts (and histology), harbor the focus more frequently than any other gland or organ.

3. A very simple tonsillitis may be followed by complications (nephritis, endocarditis, myocarditis, arthritis, etc.) so serious as to endanger life.

4. The infection may become latent, and produce serious trouble weeks or months later at a point far removed from its original site.

5. In view of an occasional general sepsis coming on after a tonsillectomy, it is necessary where possible to clear up the infection before operation with autogenous vaccines. In this way the danger of a general sepsis following tonsillectomy is eliminated.

6. Where the focus of infection in arthritis exists in the tonsil (in the case of arthritis, nephritis, endocarditis, appendicitis, etc.), the treatment should consist in the injection of autogenous vaccines until all infection is cleared up, and then the removal of tonsils by enucleation.

7. The complications are caused by an absorption of chemical toxins, rather than by a bacteriemia.

8. The blood changes seem to be in the Connellan-King diplococci infections—a simple anemia and in a few cases a slight increase in the eosinophiles 4-6 per cent.

9. In some cases symptoms other than those for which treatment was instituted have disappeared. For instance in one patient with arthritis and marked ethmoiditis, the culture was obtained from the throat. After two weeks' treatment with autogenous vaccines the arthritis was only slightly improved, but the ethmoiditis and pus in the nose had entirely disappeared. Another patient with severe gastric disturbance, who had to remain on a strict diet of certain things, was able to eat almost everything after she had taken treatment with the autogenous vaccines.

10. The treatment with the vaccines have been eminently satisfactory in a very high percentage of

all cases treated. Seventy-eight patients have now been treated by me, and there is only one who has not been markedly improved.

All of the bacteriological and laboratory work has been done by Mr. John J. Connellan of the Higgins Laboratories, and I take pleasure in expressing my great appreciation of his excellent work.

40 East Forty-first Street.

RECTAL OPERATIONS.

CONCLUSIONS DERIVED FROM A SERIES OF FIVE HUNDRED PERFORMED WITHOUT GENERAL ANESTHESIA.

By WATERS F. BURROWS, M.D.,

AND

ELLIOTT C. BURROWS, M.D.,

NEW YORK.

Rectal diseases are usually minor conditions, requiring simple surgical relief. Pain with common rectal surgery should be absent or of slight degree, the patient's life should at no time be in jeopardy, whether from ether or chloroform or from immediate or remote complications. However, the exceptions in rectal surgery to what might be reasonably expected regarding comfort and danger, have led many to dread rectal operative relief. The operations, performed under ether anesthesia are followed by pain, often severe, usually demanding morphine for its control. Deep general anesthesia is required or otherwise the rectal reflex causes, during the operation, spasm of the anal and contraction of the general skeletal muscles. Moreover, in plethoric patients or in others due to an unnatural position upon the operating table, ether anesthesia is unsatisfactory and leads to delays and dangers, which are avoided when local (novocain) anesthesia is used. Following ether anesthesia, in rectal surgery, pain occurs, voluntary urination is frequently impossible, and catheterization, with dangers of cystitis, required.

We desire, therefore, to present our experience in 500 operations upon the rectum, performed by new methods under local anesthesia. The advantages of local anesthesia in any field of surgery where applicable are obvious. Pain during the operation and after pain are avoided and detention of the patient in home or hospital even for a short time is the exception. The complications and dangers of a great part of the surgery as performed under general anesthesia do not occur, convalescence is not delayed and takes place with the patient free to attend to his usual duties. Whereas following a general anesthetic catheterization is found necessary in approximately 25 per cent. of the cases, the writers, in rectal operations performed under local anesthesia, find it unnecessary to use the catheter and urination is normal.

The rectal conditions for which operations have been performed under local anesthesia by the writers may be given in the order of their frequency, as follows: Hemorrhoids; fissure; cryptitis and ulceration; constipation, pruritus ani, fistula, abscess, prolapse of rectal mucosa; stricture of anal canal; tuberculous ulceration, fistula, or skin involvement; solitary and multiple polyps. Frequently the lesions are associated and constipation is a frequent concomitant of a number of painful and obstructive rectal affections.

Hemorrhoids, external and internal, are the most common lesions. With the latter there may be bleeding at stool, accompanied or not by prolapse of the piles and these may be voluntarily or by means of pressure forced back within the rectum. Mucus and moisture will often keep the perianal tissues soft and chronically infected, leading to burning and itching, which are increased by the congestion accompanying the trouble. Constant discomfort or rectal neuralgia is not unusual, but except in the case of prolapse, strangulated or gangrenous piles, acute pain is absent. A new method of treating hemorrhoids will shortly be described in full and needs no further attention here except to note that it is practically the only method we use and thereby clamp and cautery, needle and thread, ligature, and simple excision are relegated to the past.

Fissure, cryptitis, and ulceration in the anal canal are met with frequently. They occur as a result of trauma produced by the passage of hard bowel matter, or from the inflammation following frequent irritating movements. The characteristic feature of the affection is pain, often severe, coming immediately after a bowel movement and persisting a variable time, frequently for several hours. Streaks of blood may accompany the evacuation and complications, such as abscess, proctitis, and constipation are common. Division of some fibers of the anal sphincter, or, if multiple fissures, cryptitis, or ulceration is present, excision of the affected area will result in a permanent cure.

Constipation is a frequent accompaniment of anal lesions and a symptom rather than in itself a disease; however, local anesthesia permits the eradication of many rectal affections leading to it. Allowed to exist, even though primarily of rectal origin, it leads to back pressure upon the bowel above. The rectum and sigmoid are at first stretched and their reflex action interfered with, resulting in a residue of bowel contents and a sensation of incomplete evacuation. The former would be of sufficient gravity were it to remain an irritant in the lower bowel, but it does more, for through causing an exudate the bowel contents are softened and then forced back in considerable quantity into the colon. Thus chronic invalidism from absorption, appendicitis, and incompetency of the ileocecal valve may result. A primarily rectal affection may thereby become a source of intraabdominal disease.

Pruritus ani or itching is a frequent anal affection. It may have a basis in a constitutional disease, but is usually an indication of a local condition. It may result from anal, rectal, or bowel abnormality leading to a catarrhal or irritating discharge. With continued maceration and irritation of the perianal structures and the implantation of a chronic infection, which soon follows, the skin becomes depigmented, swollen, and thrown into folds, the creases hold moisture and bacteria, and the itching, which results from the congestion and irritation of the nerve endings in the skin, may become almost unbearable, especially at night. The writers' modification of the Ball operation, severing affected nerves subcutaneously, and the eradication of causative lesions elsewhere cure this most annoying and chronic affection.

Fistula in ano will not occur in the normal anal canal. It is an indication of previous diseased conditions which have been neglected or unrecognized. When once produced it consists of a sinus or sinuses, usually complete, extending from skin to anal canal. Either end of this tract may close spontaneously, usually temporarily, but the remainder will persist as a source of constant irritation and discharge,

causing inflammation of the rectum, anus, or surrounding skin, or, becoming blocked, small painful abscesses are formed and the tracks become more numerous and multiple openings may appear upon the skin. The condition is not usually tuberculous. Operated upon before complications have set in, fistula is a suitable field for local anesthesia and by excision or incision of the track, passing through its internal or rectal opening, cure results.

Ischiorectal abscess likewise indicates that a preexisting rectal abnormality has been present, whereby deep infection of surrounding tissues has taken place. Early incision of the abscess will usually prevent later fistula formation, but the anal abnormality primarily at fault should also be treated.

Prolapse of the rectal mucosa may be associated with piles or follow mutilating procedures, such as the Whitehead operation for hemorrhoids. Cicatricial stricture of the anal canal also frequently accompanies the same operation but may follow the use of clamp and cautery or result from extensive denudation of perianal skin and infection of these tissues. Prevention is always possible if rectal operations are properly performed, but when occurring the prolapse may be treated as a pile or the cicatrical anal ring divided.

Tuberculous ulceration, fistula, and skin involvement may be of long duration, extensive, and progressive, and the use of the actual cautery may be safest, since in eradicating lesions it seals temporarily lymph spaces and destroys tuberculous infection. General anesthesia is then demanded, but in the present age, when physical neglect is not as frequent, the deplorable tuberculous rectal infections formerly observed are the exception and the writers ordinarily use local anesthesia for such cases.

Solitary or multiple polyps, originating in rectal mucosa or anal papillæ, may attain large size, protrude from the rectum, and be mistaken for piles. Both are best operated upon under local anesthesia.

Local anesthesia is indicated in 95 per cent. of all rectal surgery. It permits painless operations free from danger, obviates the after pain of the general anesthetic, does not confine the patient to bed, but, on the contrary, interferes least with his usual routine. The time saved the patient is an important item and the proper use of the method will place rectal surgery upon a higher plane than heretofore, when, under ether anesthesia, it has often resulted in a destructive major operation.

17 East Thirty-eighth Street.

Medicolegal Notes.

Malpractice — Newly Discovered Evidence Necessitates New Trial.—In an action against surgeons for malpractice in connection with an attempted operation for the removal of a goiter, it appeared that after an incision was made the operation was discontinued, and it was the defendants' claim that this was necessary, because of the discovery of a vein in such a condition that it could not be ligated or closed by usual methods, and that it was necessary to stop the flow of blood by means of packing inserted into the incision. There was evidence for the plaintiff that the wound made by the incision had not yet healed at the time of the trial. After a judgment for the plaintiff, an operation was performed by another surgeon, who testified, on a petition for a new trial, that he discovered a malignant cancerous condition, and that this would have kept the wound from healing, and could not have been discovered by the incision made by the defendants. It was held that this was material and newly discovered evidence, entitling the defendants to a new trial, as the jury evidently believed that the failure of the wound to heal was due to the defendants' negligence or unskilful methods, while such evidence tended to show that it was due to the cancerous condition. The fact that the surgeons defended on the theory that an incision made by them was progressing nicely and would have healed if the plaintiff had remained at the defendants' hospital or given it proper attention did not prevent them from obtaining a new trial for the newly discovered evidence. —Mason, Evans & Keys vs. Meloan, Kentucky Court of Appeals, 177 S. W. 435.

Practising without License. — The Montana Statute, Rev. Codes, § 1587, provides that any person wishing to practise medicine or surgery must secure a certificate from the State board of medical examiners. Section 1591 provides that every person practising without such certificate shall be guilty of a misdemeanor, defines practising medicine or surgery, and provides that the section shall not restrain any legally licensed osteopathic practitioner. Laws 1901, p. 51, § 11, declares that the practice of osteopathy shall not be deemed the practice of medicine or surgery. In an action for practising medicine without a certificate it was held that the act relating to the practice of medicine and surgery is not unconstitutional as constituting class legislation discriminating in favor of osteopaths; they being excluded from the practice of medicine. Rev. Codes, § 1605, providing that every person shall be deemed practising osteopathy within the meaning of the act who shall treat, cure or relieve any disease, or cure or relieve any fracture or abnormal condition, by any treatment by the use of the hands or mechanical appliances, does not authorize an osteopath to practice medicine or surgery, but confines treatment to the use of the hands or mechanical appliances.—State v. Dodd, Montana Supreme Court, 149 Pac. 481.

Physical Examinations of Plaintiff Suing for Personal Injuries—How Conducted.—In an action for personal injuries the Tennessee Supreme Court was called upon to decide whether a trial court has the right to compel the physical examination of a plaintiff suing for personal injuries. Although the right is denied in Illinois, Montana, South Carolina, Utah, Texas, and in the Supreme Court of the United States, the weight of authority is to the effect that it be allowed, and the Tennessee court agreed with this opinion. In New York, New Jersey, and Florida it is authorized by statute. But in the cases which recognize the doctrine it is applied with great restraint. The plaintiff must first be asked to submit to an examination. If he refuses the court may be applied to. It must be shown that the examination must be necessary so that justice may be done to the defendant and that it can be done without danger or serious pain to the plaintiff.

If the application is granted the plaintiff cannot be required to submit his body to the examination of a physician or surgeon selected by the defendant. The physician or surgeon must be selected by the trial judge, and he must be one of competent skill and indifferent between the parties. While the expense must be borne in the first place by the defendant making the application, the fee should be fixed in advance, and paid into court, to be paid to the expert when he files his report. The expert should file a report stating in detail the result of the examination. This report should be open to the inspection of counsel on both sides, but not for use as evidence except in cross-examination of the expert, in case he should be introduced as a witness by either of the parties.

In the conduct of the examination, the privacy of the plaintiff's person must be preserved as far as possible. In the case of a woman, there should be female physicians if they are accessible. If application be made therefor, the plaintiff's own physician should be permitted to be present at the examination.—Williams v. Chattanooga Iron Works, Tennessee Supreme Court, 176 S. W. 1031.

Malpractice—Sufficiency of Evidence.—A physician and surgeon was employed to treat an infant for bronchial pneumonia. In an action for the child's death the evidence for the plaintiff showed that the defendant inserted a rubber tube in an incision made by him, leaving it unsecured, so that it slipped inside the body, and that the tube was allowed to remain there for some time. It was held that, if these matters were not the cause of the patient's death, or if the defendant's conduct was that of a reasonably skilful physician and surgeon, it was for him to put in his proof, and as he offered no evidence the jury was warranted in finding for the plaintiff.—Sontag vs. Ude (Mo.), 177 S. W. 659.

THE PROBLEM OF NEPHRITIC EDEMA.

THE edema of nephritis as well as that resulting from cardiac decompensation cannot be considered apart from changes in the blood, changes in the capillary wall, and changes in the tissues. The explanation of the genesis of both types of edema is rendered more difficult by the fact that there are types of edema that are not dependent upon renal or cardiac factors; for instance, the angioneurotic and the cachectic edemas. An interesting clinical and experimental study of this subject is contributed by Leo Hess to the *Zeitschrift für klinische Medizin*, Vol. 82, Nos. 1 and 2. At the outset he notes that the edemas occurring in nephritis are not all of the same origin. There may be an edema resulting from stasis and resembling in its course and in its occurrence in the dependent parts of the body the edema of cardiac insufficiency. In a general way the presence or absence of edema in nephritis is associated with the anatomical type of this condition, in the one instance with the parenchymatous and in the other instance with the interstitial form of nephritis. The similar rôle played by different etiological causes is illustrated by the fact that in the nephritis of pregnancy and in that following scarlet fever there frequently occurs a most pronounced edema. The nephritis following pneumonia may or may not be accompanied by edema. The question arises whether there may not be some constitutional factor that determines the presence of edema in cases of chronic nephritis. A review of the various theories that have been advanced to explain the origin of edema shows that none is entirely satisfactory for they fail to take into account all of the factors that are involved. The most important of these appears to be the capillary wall. Hess bases this conclusion upon experimental evidence. The two renal poisons, uranium and chromium, have the same action upon the epithelium of the convoluted tubules. Chronic uranium intoxication produces almost always a transudation into the serous cavities, which is not the case in poisoning with the chromium salts. It would appear, therefore, that the cause of the transudation that occurs in nephritis, at any rate, in the experimental nephritis produced by uranium, is to be sought in some extrarenal factor. Magnus demonstrated that the capillary wall during life interposes a barrier to the transudation of fluid, and that this barrier is broken down by injury or by the action of certain poisons. Hausmann showed that fluorescent substances, such as hematoporphyrin, when injected into white mice that are subsequently exposed to the light, give rise to a general edema. This effect is attributed to an injury of the peripheral blood vessels. Although uranium poisoning in rabbits causes a transudation into the serous cavities without any accompanying edema of the subcutaneous tissues, if in addition to the uranium intoxication there is produced a direct attack upon the blood vessels by means of intravenous injections of adrenalin, there results a genuine edema of the hind limbs. This experiment proves that injury of the vascular wall is a necessary factor in the development of edema.

The substances, such as chloral hydrate, chloroform, ether, and phosphorus, that are known to injure the capillary wall, belong, as a rule, to the group of so-called "lipotropic" agents, which are capable of dissolving or of being dissolved in fats and fatty bodies. The increased permeability of the capillary wall, which is the result of the above injury, is possibly to be attributed to the abstraction of some important constituent of protoplasm, such as lecithin. In the toxic anemias produced by pyrodin and m-toluylenediamine an edema of the face is an accompanying phenomenon. These poisons are soluble in lipoids as is also the aromatic amine, oxyphenylethylamine, which is found in the feces in cases of obstinate constipation accompanied by urticaria. It has been found experimentally that imidazolethylamine, which is probably a metabolic product, gives rise to local edemas. All of the above toxic types of edema are independent of any cardiac or renal factor and are probably the result of an injury of the lipoid constituents of the cells of the capillary wall.

In addition to the above analysis of the experimental studies on edema, Hess contributes the results of an important clinical study of his own on this subject. He observed a series of five cases in which the edema could not be accounted for during life entirely on the basis of renal or circulatory impairment and in which at autopsy there was found distinct evidence of an abnormal narrowness of the arterial system, or the presence of the status thymicolymphaticus. In all of these cases the edema differed from that characteristic of nephritis. It had an acute onset, persisted in spite of all treatment, and resembled in its localization the edema of cardiac insufficiency, but examination of the heart revealed either no impairment of the latter or not sufficient impairment to account for the edema. The conclusion was drawn that the condition of the vascular wall was the important factor in the production of this edema. Even in cases in which there is an obviously close connection between the edema and cardiac or renal insufficiency, the localization of the edema suggests that the condition of the vascular wall plays an important rôle. In illustration of this statement there are cited the palpebral edema of trichinosis, the pulmonary edema of Bright's disease, the premenstrual and climacteric edemas, the cerebral edema of chronic plumbism, and angioneurotic edema. One striking phenomenon frequently present in cases of nephritic edema is the persistence of this condition

in spite of a relatively good diuresis. This fact furnishes additional evidence in support of the view that the condition of the vascular wall is the important factor in the genesis of edema.

THE TOXICOLOGY OF TOILET PREPARATIONS.

EVEN to the remotest confines of the regions reached by the printed word some hint of the perniciousness of the patent medicine has spread. To be sure, potential purchases of the gold brick still throng cityward, the evasive pea refuses to stay put, the immortal come-on springs into being at the rate of sixty an hour according to a well-known authority, and farmers' wives who have done the household drudgery for a family of ten and cooked three meals for a hungry horde of hired hands continue to pinch out enough from the egg money to purchase something for "that tired feeling." But he who runs may read the death sentence of the great American fraud being slowly spelled out, letter by letter, word by word, on the wall of publicity. When we compare the restrictions under which this business is obliged to operate to-day with the license of a few years back we are justified in optimistic prophecies.

And while we are in the altruistic and probably thankless business of protecting the public against itself let us splinter a lance against another enemy, the toilet preparation fraud. Not, to be frank, that we care greatly whether my lady pays five dollars a pound for Epsom salts put up under a fancy trade name as a face bleach and bought by the trade at five cents a pound or not. If the public is sufficiently gullible to pay seventy-five cents for a shampoo the cost of production of which is about one and a half cents, what care we? Our withers are unwrung. But when toilet preparations contain deleterious substances of various kinds included because they are cheap or because they are stronger or more rapid in their actions than more innocuous substances, then it is time for us to step into the arena.

In an article on "Cosmetics as Drugs," in *Public Health Reports* for October 15, 1915, Mr. Martin I. Wilbert of the Hygienic Laboratory has pointed out a few interesting facts. His enthusiasm seems rather to carry him away in his opening sentence when he says, "Of the many and varied abuses of drug products there is none in which fraud, deception, and a wanton disregard for human health and even life are so clearly evidenced as in connection with the manufacture, sale, and use of so-called 'cosmetics.'" This is somewhat too sweeping a statement. How about the cancer and consumption "cures," the remedies for "female troubles" and all the rest of the vampire crew? But, anyway, Mr. Wilbert makes out a good case against the manufacturers of cosmetics and if he is a little too vehement in his denunciations it is a fault that savors of virtue.

One of the chief crimes of the producers of these articles is the inclusion of wood alcohol in the formula. We are all of course familiar with the toxicology of this chemical. In two States quoted, out of 147 samples of various lotions 27 were found to contain methyl alcohol. Some States even expressly permit its use in preparations intended for external use. Lead, mercury, and zinc and their salts are extensively used in face washes, enamels, etc. This in spite of the fact that much money and time are being spent to prevent poisoning from these various metals in their industrial use. It seems to be true, moreover, that these heavy metals, especially lead, are more readily absorbed through the skin by females than by males and consequently disease syndromes may arise which are difficult to recognize owing to failure to suspect their source. Wilbert mentions the investigations of LaWall, who examined sixteen samples of so-called rice powder; he found that only two were pure and that only six contained any rice powder at all. The substitutes used were chiefly talc, starch, and zinc oxide.

He concludes as a result of his studies of cosmetics that women are more susceptible than men to the injurious substances used, that wood alcohol and the salts of heavy metals should be banned entirely in the manufacture of toilet preparations, and that cosmetics should be classed as drugs and subject to the same restrictions as drugs. This seems indeed to be a logical way of considering the question. It is well known that drugs may be given by inunction and while this method does not enjoy a great deal of favor nowadays it is because of its inconvenience rather than on account of any lack of faith in its efficacy. It is noteworthy, too, that the drug which we usually think of in connection with inunction, *i.e.* mercury, is found in a great many toilet preparations intended for more or less prolonged application to various parts of the body. Those physicians who have had to place their sole reliance in mercury before the days of salvarsan and are therefore familiar with its vagaries are asked to picture the following: We will suppose a young lady about to retire for the night. She applies to her face a paste containing among other things mercuric ammonium chloride, and she uses a hair tonic containing bichloride of mercury. Her daily program includes two douches of a bichloride solution, and on this particular night, because she has not been feeling very well, she takes a rather large dose of calomel. While this is of course a heightened picture, it is undoubtedly true that ointments and lotions of various kinds containing preparations of mercury are used freely on the skin and allowed to come into contact with abraded areas. The drug is very readily absorbed under these conditions and the prodromal symptoms of ptyalism appear to the bewilderment of the physician who of course does not suspect the patient of taking mercury in any form. Plumbism occurring in the same way is even more difficult to diagnose, especially when the drinking water is absolved from suspicion.

PARATYPHOID FEVER.

THE distinctions between typhoid and the two varieties of paratyphoid fever are not as yet so marked or at any rate so generally recognized as might be desired. As a matter of fact a very considerable degree of confusion exists with regard to the diag-

nosis of the two varieties of paratyphoid fever. Dr. Henry Robinson writes on the subject in the *Lancet*, of Oct. 16, 1915, and supplies some notes on the clinical characteristics of cases treated as paratyphoid fever.

Eighty-nine cases were observed and the conclusions reached were that notwithstanding marked differences in the duration and severity of the symptoms in these 89 cases, the evidence suggested that they were manifestations of a definite clinical entity. The writer, confining himself to 47 cases in which a paratyphoid organism was isolated from the feces, blood, or urine, thought it safe to formulate the following conclusions:

(1) Paratyphoid fever, A and B, in the British Expeditionary Force, is a disease much shorter and milder than typhoid fever as met with in civilian practice and in the South African campaign. (2) Its onset may be gradual or moderately sudden. (3) Headache and abdominal pain are the most constant symptoms. (4) Shivering at the onset, cough, pains in the limbs and back, diarrhea, constipation, nosebleed are the next most common symptoms; all these are met with in about 30 to 60 per cent, of cases. Vomiting at onset and sore throat later are by no means so common. (5) Definite rose spots in successive crops are found in about 60 per cent. of cases. The abdominal reflex is absent in rather under 50 per cent. (6) The pulse rate is extraordinarily slow, even more so than in typhoid fever. (7) Relapses of brief duration are not uncommon. Several complications occur more rarely and are counterparts of those associated with typhoid fever. (8) The paratyphoid bacillus, A or B, is frequently isolable from the feces, but in many cases not until after the symptoms have subsided; one negative finding should not be accepted as conclusive. It is also occasionally isolable from the blood, urine, and metastatic abscesses. (9) Distinct help in diagnosis is obtainable from repeated quantitative Widal reactions, but much experience is required for their interpretation, and they must be read in conjunction with the clinical evidence and with the history of previous inoculation. (10) On the assumption that this disease is of the enteric group, the same precautions as in the case of the typhoid fever are indicated against its spread. In particular, carriers must be watched, for bacilli may be present in their urine and feces long after all symptoms of disease have subsided.

AN IMPORTANT EDUCATIONAL OPPORTUNITY LOST.

It is reported, as noted in our news columns, that Columbia University was unable to raise the million dollars necessary to take up the option on the property which had been selected as a desirable site for the proposed combined medical school and hospital of Columbia University and the Presbyterian Hospital, New York. This is much to be regretted, for the purchase of the property would furnish an opportunity, which can hardly occur again, to erect a great teaching and research institution on a site admirable in situation and sufficiently large for future expansion. With the growth of the city, Washington Heights will gradually become the center of population of Greater New York, and a vast clinical material would thus have been made available, for the Mayo Clinic at Rochester, Minn., has demonstrated that patients will travel any distance if they are assured of special opportunities. It is a pity that the wealthy men of New York could not in some way have met the needs of the great university in their city, and it is to be hoped that some one may yet come forward before the plot is broken up into building lots and sold. If the call had been made in San Francisco, Chicago, or Pittsburgh, it is probable that mere civic pride would have guaranteed the obtaining of the sum when it was needed.

The time is ripe for a demonstration of what can be done in the way of modern hospital construction and the scheme for the very close geographical union between the medical school and the hospital was admirable in its conception. Very few boards of trustees seem to be aware of the fact that, after all, the real laboratories of the medical school are the hospital wards, and that the hospital is more important for the achievement of scientific research in medicine than roomy laboratories and showy equipment. There is never any question when a veterinary school is started that a certain number of domestic animals are essential to the proper instruction of the pupils; but in medicine in this country the necessity for free access to the actual teaching material in the form of human beings has never been fully recognized, nor have the possibilities of such a combination as was proposed really reached their highest development. New York has long been medically less important than it should have been for this reason. It is to be hoped, therefore, that some public-spirited citizen will very promptly place Columbia in possession of sufficient funds to make it possible to obtain this remarkable site, the last plot of sufficient size available in the city.

Butter's Cancer.

Not many clinical forms of cancer have been named for individuals, although there have doubtless been plenty of opportunities for eponyms in this field. In a session last May of the Nurenburg Medical Society and Poliklinik reported in the *Münchener medizinische Wochenschrift*, Voit describes a case of so-called Butter's cancer, *i.e.* cancer of the hepatic flexure of the colon. The diagnosis was difficult. A man aged 39 complained of vague morning pains in the abdomen, relieved by eating. Appetite remained good and there was no loss of weight. Stools normal. The diagnosis was duodenal ulcer, made only after prolonged and thorough examinations. Treatment for ulcer was without benefit. Occult blood could be found at any time. Röntgen examination gave negative results. The alternative diagnosis was cancer of the right flexure which could be palpated after many attempts. Exploratory incision gave confirmatory results. The growth was no larger than a walnut and was readily extirpated. The inference from this case is very plain. If occult blood persists after the patient has been on a strict ulcer diet for a reasonable length of time, we should suspect the presence of a Butter's cancer.

A Physical Token of Epilepsy.

Experienced clinicians of past generations had certain personal criteria of suspected epilepsy such as the so-called sugar-loaf cranium. More recently a series of somatic anomalies has suggested this possibility of the so-called degenerative stigmata, with special emphasis on asymmetries of the skull and face. This has in turn lost much of its force because conspicuous asymmetry occurs in non-epileptics and even in normal subjects. Complete symmetry is in fact unknown. At a recent session of the Royal Imperial Medical Society of Vienna (*Berliner klinische Wochenschrift*, June 28) Benedikt drew a contrast between ordinary and epileptic asymmetry. The normal skull is hyperplastic to the right in the retroauricular portion of the temporal and parietal bones and the ear is placed slightly to the rear. When this arrangement is disturbed we have an anomaly, and in epilepsy this region instead of being prominent may show a flattening. Again in the normal subject the distance between the occipital protuberance and the vertex is the same as the distance between the vertex and bregma, while in the epileptic the entire distance between the occipital protuberance and bregma may be shorter than the normal by 3 cm. When a shortening of 3 cm. is obtained the subject is very probably an epileptic.

Fatal Hemorrhage as a Result of Quinsy.

One of the bugbears of the medical student of a generation ago was the supposed danger of arrosion of the internal carotid artery in consequence of peritonsillar abscess. It was on a par with the alleged risk of wounding the same vessel while opening the abscess. That such accidents did and do occur at times is, of course, not disputed. There should, however, be some particular mechanism for such happenings, and as a matter of fact such mechanism is closely associated with the formation of aneurysm of the vessel in question: Does an aneurysm of the carotid preexist in these cases, or is it the result of suppuration? It is probable that both mechanisms may be present. At a session last spring of the Gesellschaft für Natur- und Heilkunde, in Dresden (*Muenchener medizinische Wochenschrift*, August 31), Hoffmann reported a fatal case of arrosion aneurysm of the internal carotid in a boy of 13, as a complication of peritonsillar abscess. The sense of the meeting seemed to be that rupture of a preexisting aneurysm might occur in quinsy without the intermediation of suppuration, *i.e.* mere distention due to peritonsillitis could bring about rupture of an aneurysmal sac.

A Catatonic Phenomenon in the Normal Subject.

If a man stands close to the wall, an arm extended parallel to the trunk with the back of the hand pressing hard against the wall with all the muscles tense, and maintains this attitude for about a minute; and if then he turn his body a little so that the arm can move laterally, the limb automatically ascends from 0° to an angle of from 45° to 120°. The patient meanwhile feels convincingly that some one other than himself has lifted his arm. Kohnstamm made this statement at a meeting last winter of the Frankfort Medical Society (*Muenchener medizinische Wochenschrift*). He said he first had his attention called to the phenomenon by a patient, an aviator, who had discovered it in his own person. Similar phenomena can be induced in other muscular groups. In the arm experiment it is probable that the conscious volition has produced a tetanus of the extensors. The equilibrium of the muscles has been shifted, and when the arm has free play to move some of the extensors elevate it; the will impulse is outlasted by the automatic act which has the force of an inhibition. The author has not yet tested this phenomenon upon a genuine catatonic, and until this is done the relationship between the physiological and pathological phenomena cannot be determined.

News of the Week.

Doctors Sail for Germany.—A second detachment of physicians and nurses sent for relief work in Germany and Austria by the American Physicians' Expedition Committee sailed from New York on November 26 for Copenhagen. The party consisted of Dr. Frederic Kammerer, Dr. Kurt Sauer, and Dr. Frank D. Gorham, and six nurses. Dr. Frank Paschal, also a member of the expedition, sailed a few days later. The nurses will superintend a voluntary staff of nurses to be raised in Germany and Austria. The party will have an outfit sufficient to equip a hospital of 300 to 400 beds.

Hospitals for France.—Two committees have recently been formed in New York for the purpose of supplying the French Government with portable hospitals which can be carried on automobiles. The equipment in each case will consist of five machines carrying apparatus that in three hours can be set up so as to form a field hospital capable of rendering efficient service to a whole army division. One car will carry the parts of a portable operating room; another a powerful electric lighting and heating plant; a third, a laundry outfit, and a fourth and fifth, installation for couches, disinfection, destruction of vermin, and sterilization of water, shelter tents, etc.

Melba Home Hospital.—Mme. Melba, the opera singer, announced in Cleveland on November 21 that she had just arranged to give the use of her apartment in Paris for an army hospital. It will be known as the Melba Home Hospital, will accommodate 200 beds, and will be operated for the benefit of soldiers of any nationality.

American Doctors in Serbia.—Efforts are being made through the American and Bulgarian Consulates in Serbia to obtain the release of four American physicians who remained at Uskob after the Bulgarian occupation. They are Dr. S. S. Osborne of Peabody, Mass., Dr. C. E. Fox of Baltimore, and Dr. George Baehr and Dr. Harry Plotz of New York, who went to Serbia to study typhus fever.

Committee of American Physicians for the Relief of the Belgian Profession.—The treasurer, Dr. F. F. Simpson, 7048 Jenkins Arcade Building, Pittsburgh, Pa., reports a contribution of $2 from Dr. M. J. Morrissey of Hartford, Conn. The total receipts have been $7,873.84 and the total disbursements $7,310.04, leaving a balance of $563.80.

Medical Brotherhood.—Prof. Thorkild Rovsing of Copenhagen has issued an appeal to all Danish doctors to join the Medical Brotherhood organized in this country last August by Dr. S. J. Meltzer of New York, the object of which is the promotion of international comity through closer association of

medical and scientific men. The organization already has 9,000 members. No effort has been made to introduce the movement among the nations now at war, as the organization wishes to keep clear of the issues involved, with the hope that after the war is over it may be able to bring into amicable relationship the medical men of all nations and thus aid in the re-establishment of good feeling.

Health of the Canal Zone.—During the month of September, 1915, the employees at the Panama Canal numbered 34,827, and the total number of admissions to hospitals and quarters was 892, giving a rate of 307.34 per thousand, as compared with 335.44 for the preceding month and 365.70 for the corresponding month of last year. The total number of deaths among employees was 18; of these, 14 were due to disease, or 4.82 per thousand, as compared with 5.31 for the same month of 1914. Among the general population of the Canal Zone, numbering 30,219, the death rate from disease was 12.31 per thousand, or nearly a point less than for the same time last year. During the same period 49 births were reported, a rate of 19.45 per thousand, the white children numbering 16 and the colored 33; while there were among colored infants under one year of age 13 deaths, and among white children only one. The general death rate in Panama City for the month was 32.79, and that in Colon 21.27 per thousand. One case of yellow fever from Buenaventura, Colombia, developed while the patient was in the Balboa quarantine station, and death occurred a few days later. With this exception no cases of yellow fever, smallpox, or plague originated on or were brought to the Isthmus during the month.

New York's Death Rate.—The Department of Health announces that during the week ending November 20 there were reported in New York City 1,332 deaths, giving a death rate per thousand of 11.97, as compared with 1,244 deaths and a rate of 11.62 during the corresponding week of 1914. The increase in the mortality was due to diarrheal diseases, organic heart diseases, pulmonary tuberculosis, and renal diseases. The number of deaths due to contagious diseases of childhood during the week was exceedingly low, there having been but one from scarlet fever, three from measles, and five from whooping cough. The death rate for the first forty-seven weeks of 1915 was 13.57 as against 13.71 per thousand for the corresponding period of last year.

Chicago's Death Rate.—The number of deaths reported in Chicago during the week ending November 20 was 546, or 25 less than during the corresponding week of last year, the respective rates being 11.6 and 12.4 per thousand. Three deaths were reported from pellagra against one last year, and three from influenza against none last year; but in practically all other causes of death a decrease was noted.

Columbia's Option Lapses.—As a result of the failure of Columbia University to raise the sum of a million dollars by November 20, the project for establishing a great medical center on Washington Heights, New York, in conjunction with the Presbyterian Hospital has received a serious setback. The hospital and the university had together held an option, which expired on that date, on the old American League ball grounds on Broadway, between 165th and 168th streets, comprising ten and a half acres, and had the money been available for its purchase this would have been used as the site for the building of the combined College of Physicians and Surgeons and Presbyterian Hospital. Because the efforts of the university to raise its share of the purchase price were unsuccessful, the option was lost and the project has been abandoned, temporarily at least. It had been estimated that in all fourteen and a half millions would be required to carry out the plans for building and equipping the hospital, lecture rooms, student, and research laboratories, clinics, dormitories, etc., and it was felt that the plot selected was in every way suitable, as providing for future as well as present needs.

Columbia University in Brooklyn.—Beginning in September, 1916, Columbia University will give one year of college work in science and language at the Long Island College Hospital. This medical school has heretofore given a pre-medical course in physics, chemistry, biology, and a modern language, which it has required for admission to the four-year medical course leading to the degree, M.D. This course will be discontinued and Columbia University will give one year's work each in physics, chemistry, biology, French, German, and English, and these courses will have full university credit. This is in connection with the Faculty's plan to require two years of college work for admission to the medical course.

Cornell Medical College.—Cornell University Medical College has recently reorganized its surgical service at Bellevue Hospital by appointing a "visiting surgeon in charge," with a continuous service, and two associate visiting surgeons who are on a full-time salary basis, each having the care of one-half of the service and the assistance of four junior surgeons who are also surgeons to the Out-Patient Department. There are also two visiting surgeons who have a continuous service limited to some special subdivision of general surgery. In addition, there has been established a laboratory of surgical pathology and a laboratory of experimental surgery, each under the charge of a full-time salaried man. These laboratories are open to all members of the staff, who have the privilege of working on their individual problems. All the members of the hospital staff also hold positions in the Department of Surgery at the College, and the students take a portion of their surgical ward work under this organization. The essential changes from the system formerly in vogue consist in the single head, the continuous service, the full-time salaried surgeons, and the laboratories under the immediate jurisdiction of the surgical service, all of which tend to efficiency in both teaching and research.

Memorial to Dr. Blackwell.—There has recently been placed in the New York Infirmary for Women and Children a beautiful tablet as a memorial to Dr. Emily Blackwell, who with her sister, Elizabeth, founded the hospital. The bronze medallion on the tablet is the work of Victor D. Brenner of New York, who has executed bas reliefs of many prominent Americans.

Honor Their Veteran Colleagues.—The Plymouth District Medical Society, on November 23, gave a dinner at Brockton, Mass., in honor of five of its members who had practiced medicine for fifty years or more. The five were Medical Examiner A. Elliot Paine, Brockton; Dr. Calvin Pratt, Bridgewater; Dr. Samuel H. Durgin, Duxbury; Dr. Edward Cowles, Plymouth, and Dr. Horatio F. Copeland, Whitman. All are veterans of the Civil War.

Women and Medical Education.—The trustees of the University of Maryland now have under consideration the question of whether or not women

shall be admitted to the Medical School, a number of applications from women having been received. Since 1910, when the Woman's Medical College of Baltimore became extinct, there has been an increasing demand in Baltimore for a medical course for women with entrance requirements not so high as those of the Johns Hopkins Medical School. The University of Maryland at present requires one year of academic work for admission to the Medical College, and has already opened to women its courses in dentistry and pharmacy.

Twilight Sleep Films Fail.—The attempt made by the Motherhood Educational Society, Inc., to educate the New York public in regard to Twilight Sleep by the means of moving pictures, ended in the bankruptcy court recently. The society had planned to send the films around the country in charge of a physician from Freiburg, Germany, who would deliver a lecture while the pictures were being shown.

New Home at Sea Breeze.—The New York Association for Improving the Condition of the Poor has recently opened a new convalescent home for wage-earners at Sea Breeze, Coney Island. Opportunity will be given here for rest and complete recovery for wage-earners who might otherwise be forced to return to work before a cure was effected.

Decrease in Typhoid Fever.—The number of cases of typhoid fever in New York State during the month of September, 1915, the time of year when the high water mark for the disease is generally reached, was 833, which is a lower figure than that recorded for the same month of any year for which records have been kept, according to an announcement of the New York State Department of Health.

Vaccines in Typhoid Fever.—The Evans Memorial for Clinical Research of the Massachusetts Homeopathic Hospital, Boston, is collecting statistics concerning the efficiency or non-efficiency of bacterial vaccines in the treatment of typhoid fever, and is prepared to furnish blank forms upon which reports of cases so treated may be made. Application for these forms should be made to Dr. W. H. Watters, 80 East Concord street, Boston, Mass., who will be glad to hear from any physician having experience along this line, whether in few or many cases.

Health Board Supreme.—An important decision as regards the powers of the Department of Health of New York City was rendered by the Court of Appeals recently, in the case of an appeal against the enforcement of the dog muzzling order. In upholding the ordinance, the Justice said in part: "A statement of the sections of the charter, necessarily brief and epitomized, enforces two conclusions—the one, that the Legislature empowered the Board of Health to enact and enforce regulations and ordinances, in order that the public health and comfort should be protected and promoted, in relation to very many subjects and matters over which the Board of Aldermen or other municipal body are given by charter regulative power and control; the other, that the lawful regulations, ordinances and orders of the Board of Health are superior and paramount."

The Production of Radium.—Five grams of radium, it is announced by the Secretary of the Interior, have already been extracted from American ores at the Denver experiment station of the Bureau of Mines, and half of it has been delivered to the General Memorial Hospital in New York and half to Dr. Kelly's hospital in Baltimore, for the purpose of carrying on experimental tests of its therapeutic value. The cost of production of the radium was about $37,000 a gram.

Dispensaries for the Insane.—The New York State Hospital Commission has decided to establish an additional number of dispensaries in connection with the State Hospitals for the Insane, and to employ adidtional field agents as a means of curbing the spread of insanity and provide a cure. The Commission feels that it must place greater emphasis than previously on out-patient observation, after care, and preventive work, in connection with the State Hospitals, and the plans have the indorsement of Governer Whitman, who has agreed to the establishment of at least one dispensary with an active field worker for each State Hospital as soon as it can be brought about.

New Home for Convalescents.—As a memorial to her husband, Mrs. I. L. Rice of New York is preparing to build and equip a home to be known as the Isaac L. Rice Hospital for Convalescents, which will be administered by the Beth Israel Hospital Association and will be used chiefly as a home during convalescence for the patients of that institution. The estimated cost is $1,000,000. Tentative plans have been drawn and a suburban site has been selected. Although not an integral part of the Beth Israel Hospital, the home will be in close connection with it and its physicians and nurses will be drawn from the hospital, and the memorial building will make possible the limitation of the work of the Beth Israel to the treatment of acute cases. Work has already been begun on the new ten-story building for the latter institution at Livingston place and Sixteenth street which, as previously announced, will have accommodation for 500 patients.

Personals.—Dr. ROBERT BÁRÁNY of Vienna, the winner of the Nobel Prize in medicine, is reported a prisoner in Russia. He had been in charge of a field hospital at Przemysl, and was held when the Russians captured that stronghold last March.

Dr. KARL H. VAN NORMAN, former first assistant at the Johns Hopkins Hospital, has accepted a captaincy in a Canadian regiment.

Dr. WILLIAM H. WELCH of Baltimore, Dr. Simon Flexner, director of the Rockefeller Institute for Medical Research, of New York, and Dr. Wallace Butterick, director of the China Medical Board of the Rockefeller Foundation, were the guests of honor at the dedication recently of the new Sleeper-David Memorial Hospital at Pekin, China. The hospital is a five-story structure erected by the Methodist Episcopal Church at a cost of $180,000.

Dr. GEORGE G. EITEL of Minneapolis was the guest of honor at a dinner given at the Minneapolis Athletic Club on November 17 by a hundred of his friends.

Medical Society Elections.—SECOND COUNCILOR DISTRICT OF THE OHIO STATE MEDICAL ASSOCIATION: The annual meeting of this society was held at Dayton on November 15 and 16, officers being elected as follows: *President*, Dr. W. B. Patton, Springfield; *Secretary*, Dr. A. O. Peters, Dayton; *Treasurer*, Dr. W. F. Prather, Dayton.

PENOBSCOT COUNTY (ME.) MEDICAL ASSOCIATION: The annual meeting was held in Bangor on November 16, the following officers being elected: *President*, Dr. E. B. Sanger; *Vice-President*, Dr. J. B. Thompson; *Secretary-Treasurer*, Dr. H. J. Milliken.

HARDIN COUNTY (KY.) MEDICAL SOCIETY: At the annual election held at Elizabethtown recently

the following officers were chosen: *President*, Dr. M. S. Allen, Stithton; *Vice-President*, Dr. C. W. Rogers, Rineyville; *Secretary*, Dr. W. F. Alvey, Elizabethtown.

The Idaho-Oregon District Medical Society was oganized at a meeting held in Ontario, Ore., on October 30, when the following officers were elected: *President*, Dr. R. O. Payne, Ontario; *Secretary*, Dr. W. J. Weese, Ontario.

St. Louis County (Minn.) Society: Annual meeting at Duluth on October 14. Officers elected: *President*, Dr. D. L. Tilderquist, Duluth; *First Vice-President*, Dr. N. D. Kean, Coleraine; *Second Vice-President*, Dr. L. Q. Greeley, Duluth; *Secretary*, Dr. L. A. Barney, Duluth.

The Montana-North Dakota Medical Society was organized at a meeting of physicians from counties in northwestern North Dakota and northeastern Montana in Williston, N. D., on October 25, the following officers being elected: *President*, Dr. M. E. Trainor, Williston; *Vice-President*, Dr. C. Hagen; *Secretary-Treasurer*, Dr. F. W. McManus; *Directors*, Dr. L. B. Docterman, Dr. J. Drake, Mondak, Mont., and Dr. F. O. Brigham, Stanley, N. D.

The Late Dr. Huddleston.—At a recent meeting of the New York Academy of Medicine, the following minute was adopted:

"The New York Academy of Medicine has learned with sincere sorrow of the untimely death of Dr. John H. Huddleston. For three years assistant secretary, ten years recording secretary, and for the last three years trustee of this institution, Dr. Huddleston served the Academy of Medicine in the wholehearted, faithful way in which he did everything which came to his hand, performing not only the regular duties of his office, but giving much time, thought, and energy to the many committees on which he was appointed. His lovable personality and genial manner endeared him to those Fellows with whom he was brought into intimate contact, while his scholarly attainments and broad grasp of the principles of medical science commanded the respect of the whole Academy. To the trustees and to the council his sound judgment and firmness of character were of inestimable value, while their deliberations were enlivened by his genial companionship. In his death this academy and the medical profession have suffered a great loss, and it is but fitting that we record the affection and esteem which we felt for Dr. Huddleston by spreading this resolution on our minutes and sending a copy to his family and to the medical press."

The Late Dr. Trudeau.—The medical staff and the patients of the Workmen's Circle Sanatorium of Liberty, N. Y., at a meeting held to commemorate the death of Dr. Trudeau unanimously adopted the following resolutions:

Whereas, The medical staff feels that by the death of Dr. Trudeau the medical profession has been deprived of a great scientist, pathfinder, and pioneer in the sanatorium treatment of tuberculosis, and,

Whereas, The patients and medical staff deeply regret the loss of a great physician to whom an innumerable host of afflicted owe their usefulness, and,

Whereas, The patients and medical staff deem it their duty to honor the name of the great philanthropist and humanitarian, one who, though himself tuberculous, had for thirty-one years worked untiringly and unselfishly in the interests of the consumptive working men and working women, be it

Resolved, That we express our appreciation of his great work by conferring upon our hospital building the name "TRUDEAU," and, be it further

Resolved, That copies of the resolutions be sent to the medical press and a copy also be sent to the family of the deceased.

Signed, Dr. B. S. Antonowsky,
Medical Director, Pro Tem.
Dr. Julius Halpern,
Visiting Physician.

Obituary Notes.—Dr. Benjamin Joy Jeffries of Boston, Mass., a graduate of the Harvard University Medical School, Boston, in 1857, a member of the American Ophthalmological Society, the New England Ophthalmological Society, and the Massachusetts Medical Society, and formerly ophthalmologist to the Massachusetts Charitable Eye and Ear Infirmary, and consulting ophthalmologist to the State Hospital at Tewkesbury and the New England Hospital for Women, died at his home on November 21, aged 82 years.

Dr. Ira Morton Martin of Green Bay, Wis., a graduate of the Kentucky School of Medicine, Louisville, in 1891, and a member of the State Medical Society of Wisconsin and the Brown-Kewaunee Counties Medical Society, died suddenly at his home, from heart disease, on October 24.

Dr. Norton Jerome Sands of Port Chester, N. Y., a graduate of the College of Physicians and Surgeons, New York, in 1868, a member of the American Medical Association, and the New York State and Westchester County Medical Societies, died at his home after a short illness, on November 13, aged 70 years.

Dr. William Francis Knox of McKeesport, Pa., a graduate of the University of Pennsylvania, Department of Medicine, Philadelphia, in 1854, and a member of the American Medical Association, the Medical Society of the State of Pennsylvania and the Allegheny County Medical Society, died at his home on November 12, aged 84 years.

Dr. Charles A. Church of Passaic, N. J., president of the American Association of Orificial Surgeons, a graduate of the New York Homeopathic Medical College and Hospital, New York, in 1871, surgeon and chief of the gynecological staff of St. Mary's Hospital, and a member of the American Institute of Homeopathy, the Academy of Pathological Science, the New Jersey Medical Club, and the New Jersey State Homeopathic Medical Society, of which he was also president, died at his home, after a short illness on November 13, aged 75 years.

Dr. Howard J. Lee, formerly of Cleveland, Ohio, a graduate of the University of Wooster, Medical Department, Cleveland, in 1876, and a member of the American Medical Association, died at his home in St. Johnsbury, Vt., suddenly, on November 5, aged 64 years.

Dr. Oswald Wayne Smith, superintendent of Harper Hospital, Detroit, Mich., a graduate of Washington University, Medical Department, St. Louis, in 1902, formerly superintendent of the St. Louis City Hospital, an authority and writer on the subject of hospital management, died from apoplexy, after a brief illness, on November 12, aged 39 years.

Dr. Harry Daniel Reutter died at Duncannon, Pa., on October 30, at the age of 54 years. He was graduated from Jefferson Medical College in the class of 1884.

Dr. J. R. Sample of Summit, Miss., a graduate of the New Orleans School of Medicine in 1866, died at the home of his daughter in Jackson, Miss., from acute indigestion, after a brief illness, on November 8, aged 74 years.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

GENERAL MEDICAL COUNCIL — RECIPROCITY WITH COLONIES—FUTURE SUPPLY OF PRACTITIONERS—REGISTRATION CORRECTIONS—EDUCATION IN ETHICAL RELATIONSHIPS—WAR HONORS—OBITUARY.

LONDON, Nov. 12, 1915.

THE General Medical Council has just held its one hundred and second session. A new member was Prof. Harvey Littlejohn. Absent members, Sir C. Ball (on account of illness), Sir Isambard Owen and Dr. Russell (on public duties elsewhere). The meeting was held rather earlier than usual. The new building is approaching completion and it is hoped may be partially ready for occupation next month. So it may be assumed that the last session has been held in the premises which have served for half a century. No change has occurred in the membership, but Sir T. Fraser is about to retire after representing the University of Edinburgh for ten years. He took an important part in the preparation of the new pharmacopœia, which has been generally adopted throughout the empire and attained a circulation of some 25,000 copies. Professor Littlejohn, one of the new members, will take Dr. Fraser's place. Dr. Saundby's term of office having expired, he was reelected. Arrangements have been concluded for sitting members to continue in office to the end of 1916, in order that in future the elections of direct representatives may recur at regular intervals of five years. Even if an unexpected vacancy should occur no isolated election need be held in 1916, so that the council will be spared the expense and registered practitioners the distraction of such election in the coming year. Under the authority of the Privy Council the next term of office of each of the six direct representatives will begin with the year 1917, and if no casual vacancies occur succeeding elections will again come into line.

Sir Donald MacAlister, president, remarked on the medical problems of the war as pressing on the thoughts and energies of the profession as more men and still more answer the call of the King, more surgeons being needed for military service, as during the next few months it is anticipated that every qualified man of suitable age and fit for work in the medical corps will be needed. The medical war committees in England and Scotland have undertaken the organization of the profession to this end, and are making progress in their difficult task. They are calling on the young practitioners to give up private practice for war service, on those who remain behind to undertake additional work and responsibility, that the civil population may not suffer. Local medical committees are endeavoring to promote equitable agreements between those who go on active service and their colleagues who remain at home. It is on every ground desirable that such arrangements be generously adopted, and no doubt it will be by the great majority, for failure would be regarded as dishonorable. The country looks for unselfish cooperation of all classes in the common task, and the medical will not be wanting. As to the future supply of qualified men, the reciprocal arrangements with Canada are making good progress, but applicants for registration should be notified that they must not only hold the recognized diploma of their provincial university or college, but must be legally entitled to practise in that province. This is a condition of reciprocity by both imperial and colonial law, and neglect to observe it will cause delay.

There has been much talk, both inside and outside the colleges, as to the duty of students—should they interrupt their curriculum and enlist, or steadily pursue their studies until qualified to practice? Many young men are leaving the schools and enlisting, and a prospective shortage of practitioners is probable. Probationers have been employed to a considerable extent in the naval service, and have done much good work, but it is obvious that they would be of more service if qualified, and after their experience in the fleet it is to be hoped every facility will be afforded them for taking a diploma. The usual requirement of eight months' work as a messer may be thought fulfilled by the service of a probationer. The absence of civil practitioners who have gone to the front has led to fuller employment of certificated midwives, and an extension of the course of instruction for them has been submitted by the Central Board and transmitted to the Privy Council for approval. In some cases of misconduct names have been erased from the register, and it has been discovered that persons thus disqualified have removed to another part of the empire and there practised, obtaining local registration from their forfeited qualifications. The Colonial Office transmits copies of the erasure list for confidential use by Government officers in the oversea dominions, but it appears that in some cases the list had not arrived.

Part 2 of the Medical Act, 1886, having been extended to Ontario, the president has exercised the powers it confers upon him, and registration is now being carried out of the qualified practitioners in the Province. In regard to Saskatchewan, there was a good deal of correspondence involved, but it eventuated in the registrar being instructed as to the license to practise granted in the province being admitted to the colonial list of the registrar under Part 2 of the Medical Act.

Dr. Saundby, on reelection to the council, was reappointed a member of the committees on examinations, penal cases, prevention of unqualified practice, and on the national insurance act. Applications for registration took up a good deal of time. Some of these arose from the applicants' neglect to take the step until after the appointed day and continuing to practise while unregistered. It might be considered not unfair to increase the fee in such cases. There was a long discussion on the resumed consideration of the motion that "it be remitted to the education committee to report on the education of medical students in the ethical relationships of practitioners to the State, to their patients, and to each other." After defeat of several amendments, the resolution was carried.

The Distinguished Service Order has been awarded to five medical officers at the front, and the Military Cross to nine others.

Four medical officers and twenty-eight nurses have gone from London to Petrograd to serve in the Anglo-Russian Hospital there.

Dr. Addison died on the 27th ult. at Colchester, where he had practised for nearly thirty years.

Dr. Dent has died at the age of 48 at Woodford, where he had practised for about twenty years and was on the staff of the local hospital.

1. Address. The Midwife Problem. A. K. Paine.
2. The Pregnancy Clinic and the Midwife: A Comparison. James Lincoln Huntington.
3. Clinical Records in Relation to Teaching and Research. Eugene S. Kilgore.
4. The Nomenclature and Classification of Diseases. James L. Whitney.
5. Gemmatous Cervical Adenitis. William Pearce Coues
6. Local Anesthesia in the Radical Cure of Hernia. Albert Ehrenfried.
7. Studies in Speech Disorder. Walter B. Swift.

1. **The Midwife Problem.**—A. K. Paine analyzes the information which he has secured on this subject through an extensive communication with various people interested in the midwife problem throughout the United States, including leaders in the practice of obstetrics, officials whose work brings them into close contact with obstetrical problems, boards of registration in medicine, boards of health, and various local organizations. From the impressions gathered from this wealth of material the writer concludes as follows: 1. Education in obstetrics in the various medical institutions in this country is considerably below the standards achieved in other branches of medicine. 2. The practice of obstetrics generally is very materially below the standards of general medicine and surgery, due first to the educational deficiency in this subject; second, to a low type of midwife service, the result of a practical absence of regulation; and third, due to the fact that the general attitude of the public at large toward the practice of obstetrics is not in keeping with the dignity of that subject. 3. That no comprehensive and far-seeing plan is generally being developed to cope with the situation as it presents itself. 4. That there is a distinct tendency in many quarters to adopt the midwife as an institution, after the manner of its conduct in the countries of Europe. 5. That, while the whole subject of the proper obstetric care of patients needing this service is one of great economic importance to the State, there is practically no attempt at meeting this situation by the State. 6. That it would seem that our method of government is not adapted to the rigid requirements which the properly regulated midwife demands. 7. That the State should assume the management and control of this work, which is of the greatest economic importance, as readily and as well as it assumes the burden of caring for such of its citizens as are incapacitated by ill health or age.

2. **The Pregnancy Clinic and the Midwife: A Comparison.**—James Lincoln Huntington outlines the difficulties that would have to be surmounted before the midwife could be educated in Massachusetts. While it would not be difficult to establish the machinery for licensing the midwife, such a law under present conditions would be futile. All the women practising as midwives are breaking the law now, yet very few are prosecuted annually. Again, law that is not backed by public sentiment is futile and public sentiment in Massachusetts is absolutely indifferent as to whether midwives practice or not, or whether they are or are not licensed. Furthermore, by developing a midwife system a dual standard is established in obstetrics. We have been told that the immigrant cannot be weaned from the midwife, but that she not only can be, but had been, weaned from the midwife can be seen by the casual observer who will visit the pregnancy clinic of the Boston Lying-in Hospital. This institution was started in 1911 and there are now three similar clinics in Boston, besides others in smaller cities. All patients are urged to come to the clinic as early in their pregnancy as possible, and every year more patients are coming before the fifth month. During 1914 there were 2,067 women under the care of this clinic. The work of such an institution is educational. The writer says: "We teach the community to appreciate good obstetrics, teach our patients how to obtain this care, and our students how to provide it. We feel confident that this is the solution of the obstetrical problem in Massachusetts, offering far better results than could the midwife, no matter how well trained and regulated. By the increase in the number of such institutions we are encouraged to believe that the midwife will gradually disappear, being superseded by the modern obstetrical dispensary."

3. **Clinical Records in Relation to Teaching and Research.**—Eugene S. Kilgore reported, in connection with the reorganization of the University of California Hospital in 1912, his experiences in the cooperation of a university hospital, medical school, and training school for nurses, to promote accuracy and completeness of clinical records. He offers suggestions concerning the methods of recording certain data, which will be taken up in other articles. In addition to the usual diagnosis index, which should be made to include many more of the secondary diagnoses, a plan is described for indexing any clinical facts which cannot be included among the diagnoses. This is as simple as it can be and yet give the results, and it works well.

6. **Local Anesthesia in the Radical Cure of Hernia.**—Albert Ehrenfried finds that local anesthesia can be employed in the operative treatment of inguinal hernia with considerable satisfaction. He reports three cases, coming under his observation in a week in which general anesthesia was contraindicated and the results of local anesthesia were particularly gratifying. He finds in novocaine a simple and satisfactory means of inducing anesthesia for the radical cure of inguinal hernia. The technique adds something in the way of difficulty to the surgeon, who is not accustomed to the use of local anesthesia, but the advantages to the patient are sufficient to compensate for any extra care or labor required. The writer believes that if the line of incision is first injected endermically, the surface anesthesia will be more assured, much less solution will be required in the subcutaneous tissue, as a consequence of which there will be much less distortion of the field, and the incision can be started without waiting as soon as the injection is completed.

7. **Studies in Speech Disorder.**—Walter B. Swift discusses the vocal defects that persist after adenoid and tonsil operations, and points out that they are quite various. The treatment varies with every case. Even some cases with the same defects have to be approached differently from others because of their different dispositions. Otherwise the treatment consists in reteaching vocal expression through imitation and didactic instruction. Vocal drill by one trained scientifically in the understanding of speech disorder is the surest method to secure permanent relief and to attain a perfect articulation.

3. **Parapsoriasis.**—Fred Wise discusses this disease from the clinical and diagnostic standpoint and reports five cases encountered during the past two years in private and dispensary practice in New York, so that

he concludes it can scarcely be said that the disease belongs to the very rare dermatoses. Unfortunately the nomenclature of these polymorphic cutaneous affections is in a chaotic condition. However, Brocq has introduced the name parapsoriasis for that group of diseases of the skin characterized by persistent, red, scaling patches, or lichen, planus-like lesions devoid of subjective sensations and resistant to therapeutic measures. Taking the five cases which he reports collectively the author finds that the changes depicted in them deviate hardly at all from those noted by Fox and Macleod which were characterized by dilatation of the subepidermal capillaries; flattening of the papillary bodies; edema affecting the fibrous stroma near the dilated vessels; edema and rarification of the collagen; infiltration of the small cells like lymphocytes with a few small polymorphonuclear leucocytes among them; thinning of the overlying epidermis; interepithelial edema and presence of leucocytes; edema of the granular cells. There was no stratum lucidum detected; the stratum corneum showed a tendency to desquammate; only here and there could imperfectly cornified cells be found retaining nuclear remains, and where these latter cells were present, the granular layer was deficient. The elastin did not stain well. As to the mode of production the consensus of opinion is that the alterations in the epidermis are of secondary character. The primary changes take place in the upper portion of the cornium. It is also believed that chronic vasomotor disturbances induced by toxic products play a dominating part in the pathogenesis of the disease. The history of the treatment in these five cases seemed to confirm the futility of ordinary measures; two of the cases seemed to show some response to serum therapy though it was too soon to state that they were definitely cured.

5. **The Artful Acarus.**—William P. Cunningham apologizes for retelling the oft-told tale of scabies, but states that the frequency with which this condition remains unidentified and uncontrolled is warranty enough for the revival, circumstantial description, and reiterated emphasis on this subject. The characteristic and in fact the only lesion produced by the acarus is the furrow and the reason it is not recognized is because it is not thought of. In order that treatment may be speedily effective it is necessary not only to destroy the parasite in the skin, but also in the clothing. Hence the underwear must be boiled before it can be worn again. Wristbands and collars of coats must be soaked in naphtha or the whole garment sterilized by heat. The patient must take a hot bath and rub himself vigorously with common brown soap to open up the furrows. He must soak in hot water for half an hour. Then he must rub in a parasiticide for half an hour longer. He must then put on a suit of underwear perfectly new or sterilized by boiling. Every night and morning he must rub in the ointment designed to destroy the acarus. At the end of the third day he takes another hot bath and puts on sterilized underwear. If he has been vigorous and faithful he will be cured. If any furrows have escaped the process must be repeated. Sulphur is the great acaracide. Storax and tar are likewise effective, and a combination of the three may be used with advantage.

8. **Acute Otitis Media.**—Clarence H. Smith reports a case of pyemia of otitic origin which is of interest because of the youth of the patient (seventeen months), the difficulties of diagnosis, and the measures of treatment. The child had been ill since May 22, 1915, with influenza, bronchopneumonia, tonsillitis, and double acute otitis. The ear symptoms were first noticeable on May 27, and the first metastasis was observed on June 1. There was an absence of symptoms of mastoiditis, and at operation there was found a freedom from pathological changes in the mastoid. There was an extensive sinus thrombosis, which certainly reached as far back as the torcular; how much further it was impossible to say as the distal end was not reached at the operation. Fortunately this was absorbed and did not act as a continuing source of infection. There was an abscess in the right great toe, one over the elbow, and over a dozen superficial ones in various parts of the body. Transfused blood was used to counteract the septic anemia, and proved of very material benefit in this instance, as after its use an immediate improvement in the color of the patient and the quality of the pulse was seen. The writer called attention to this transfusion as a measure hitherto not often used in aural surgery.

9. **Potassium Permanganate in the Examination of Cerebrospinal Fluid.**—A. I. Rubenstone says that in frank meningitis we already have enough diagnostic and corroborative methods to ascertain the type of meningitis without much difficulty, but meningeal irritation due to some toxic agent which is present in the body which finds its way into the cerebrospinal fluid may not give us chemical evidence of its presence in the cerebrospinal fluid. In such cases the writer has found the following test advocated by Boveri very useful: To 1 c.c. of cerebrospinal fluid in a test tube add 1 c.c. of 0.1 per 1000 potassium permanganate and shake well. Pathological spinal fluid produces a bright yellow color, while normal fluid retains a pinkish violet tinge. In an examination of over 100 specimens of spinal fluid by this test the author has found that by the use of double the quantities originally advocated the color reactions are much easier to interpret and that there is a definite ratio between the color changes and the abnormal state of the fluid. Fluid from undoubted cases of meningitis, tuberculous, syphilitic, or suppurative, almost immediately turned the reagent a bright yellow, while mild cases of meningeal irritation did not decolorize the reagent until two or three minutes after the admixture. The writer concludes that while potassium permanganate test is not of specific value in the diagnosis of pathological conditions of the spinal fluid, yet it should take a place as an addition to our list of reactions, because it is not only useful in corroborating other chemical tests of the severity of the disease process, but in doubtful cases may serve as a deciding factor in the differentiation between absolutely normal and mildly abnormal spinal fluids.

1. The Relation of Rodent Plague to Human Infection.—W. C. Rucker believes that the most essential factor in the control of plague during recent years has been the realization that it is essentially a rodent epizootic. The literature of plague contains reports of the disease in various animals, but many of these reports are not confirmed by convincing experimental evidence. The rôle of the rat in the pathogenesis is classical and there is a preponderance of evidence which proves that bubonic plague in man depends on the presence of the disease in rodents. The overwhelming fact in plague perpetuation and spread is that it is a rodent disease and it is interesting to study the relation of the distribution of human plague cases in their relation to rodent plague cases. Since plague is a rodent disease, if man is isolated from rodents he will not under ordinary circumstances contract the disease. It is manifestly impossible to kill all of the rats in a given community, much less in a whole country, or the entire world. If their migrations can be controlled, if they can be excluded from the places in which man lives and works, the maximum result has been accomplished.

6. Blood Cryoscopy and Blood Urea.—Martin Krotoszyner and George W. Hartman make a comparative study of the renal function with both tests and conclude that (1) blood cryoscopy and blood urea run parallel in cases with normal renal function; (2) in renal insufficiency pathological or high points are obtained with both tests; (3) the limited range between normal and pathological points, while rendering technique of cryoscopy more difficult, increases its delicacy and prognostic significance; (4) blood urea, while technically simpler, is, on account of the broad range of its normal and pathological values, prognostically less precise; (5) simultaneous application of both tests intensifies, in doubtful cases, the significance of findings.

9. Viability of Bacillus Typhosus in Ice Cream.—O. W. H. Mitchell says that the use of various frozen foods and confections in which milk and milk products serve as a basis or constituent has become so great as to demand serious attention from sanitarians. The persistence of the typhoid bacillus in milk and milk products is well known, and many cases and epidemics are recorded which have been transmitted by this food. The *Bacillus typhosus* survives in ice cream for varying lengths of time, in the recorded experiments from 12 to 39 days. It is plain, therefore, that ice cream may easily transmit typhoid fever. The findings emphasize the necessity of strict cleanliness in the manufacture of ice cream, and the importance of pasteurization of milk and milk products used in these mixtures.

10. Typhoid Fever Resulting from Infection of an Unpasteurized Milk Supply.—Don B. Lowe reports a series of five cases to emphasize the dangers of an unpasteurized milk supply and the necessity of reporting contagious diseases to the proper authorities.

11. Destroying Limited Obstructive Glandular Growths in the Posterior Urethra by the High Frequency Current.—Robert V. Day reports several cases occurring in the private practice of Dr. Granville MacGowan and himself. Out of 39 cases of intraurethral or bladder neck cautery operations during the past 13 months, 31 were by either the simple electric cautery or high frequency cauterization with flexible electrodes; 8 were done by the silica insulated wire needling and bipolar current. Only selected cases were chosen for this method. Of the 8 cases detailed there were 2 failures and 6 successful operations. In conclusion he states that a much greater amount of tissue can be cooked at a sitting than by ordinary high frequency methods; the point of application can be made to better advantage in some cases—especially when the urethra is somewhat choked; masses can be made to slough which could hardly be impressed by the usual procedures; and there is little fear of even slight hemorrhage and very little postoperative reaction.

14. Structural Changes in Congenital Hip Dislocation.—Wallace Blanchard says that experience with these cases seems to warrant the following conclusions: A shortened or twisted neck in a coxa valga position may look unpromising in the roentgenogram, and yet present no bar to a good reduction and ultimately to a good functioning joint. Eight months is the shortest time in which a dependable acetabulum reforms, and any radical change in the position of the leg interrupts the rebuilding process. The best functional result may be obtained in children from 3 to 5 years of age and with from 2.5 to 4 c.m. of shortening. There is no age limit upward; the older the child the greater the shortening, the more secure the replacement, if it can be made. The difficulty of reduction increases with the shortening after 4 c.m. have been passed. Reduction should be delayed in all cases of 3 years or younger and in those that show 2 c.m. or less of shortening. If the roentgenogram shows delayed ossification from rickets or other causes, the reduction must be postponed. Perfect or satisfactory function may be obtained in a large majority of the unilateral and a fair proportion of the bilateral cases.

15. The Significance of the Fixation of Certain Abdominal Organs in the Human Body.—Robert C. Coffey concludes as follows: 1. Prenatal fixation of the pancreas, duodenum, ascending and descending colon, and their mesenteries to the parietal peritoneum; of the liver to the diaphragm; of the omentum to the transverse colon; and the obliteration of the omental bursa, are evolutionary changes which help to fit man for the erect posture are not found in quadrupeds. 2. All cases of floating kidney with general visceroptosis are found in patients whose ascending and descending colon with mesenteries have failed to properly adhere to the parietal peritoneum. Surgical fixation of a floating kidney without fixing the colon is not based on sound surgical and anatomical principles; hence the failure of such operations in the past and necessity for surgical fixation of the colon at the same time. 3. Many cases of intestinal stasis are caused by the disturbed relations of the parts of the intestinal tract resulting from normal fixation of the ascending colon. While most of such cases are relieved by medical means, a few require surgical fixation. Surgical fixation of the ascending colon should be extended to the suspension of first portion of the transverse colon by the omentum, for purpose of preventing harmful angulation at the hepatic flexure. 4. Some cases of persistent stomach trouble are due to the weight of a distended mobile cecum dragging on the third portion of the duodenum, and are relieved by anchoring the ascending colon and suspending the first half of the transverse colon.

4. The General Surgery of Gunshot Wounds of the Nerves. Wilfred Trotter.
5. Experiences in Serbia. J. T. J. Morrison.

3. Gunshot Injuries of Nerves.—Frederick Eve and R. S. Woods state that 28 cases were operated on at the War Hospital at Croydon, five for injuries of the brachial plexus, eight of the musculospiral nerve, one of the posterior interosseous nerve, five of the ulnar, two of the median and ulnar nerves together, and seven of the sciatic or external and internal popliteal nerves. The five cases of injury to the brachial nerve furnished many points of interest. They found that where a dense mass of cicatricial tissue had matted together all the cords of the brachial plexus and was adherent to the anterior aspect of the subscapularis muscle that by cutting combined with teasing by blunt dissection the various strands of the cord could finally be separated out and the cicatrical tissue removed. Boldness is justifiable in operating on these severe lesions, for the limb must remain useless unless restoration of conduction in the nerves can be restored by surgical measures. The chief point in the operative treatment of these nerve lesions is to determine whether simply to separate the injured nerve from the surrounding tissues or to resect it, and this is of greater importance owing to the fact that anatomical division is comparatively rare. A definite indication was usually afforded by inspection. In those cases in which resection was performed the fibrotic tissue or bulbous end was removed on the proximal side until the section showed well-defined nerve bundles, and the distal end was refreshed. The ends were pierced with a round shafted needle and united with one or, in the case of large trunks, two sutures of 20 day chromic catgut, 0 or 1 size. It was always found possible to get the ends of the nerves together by freeing the nerve above and below and flexing the nearest joint or adducting the upper arm. Where a portion of the nerve was thickened and appeared to be "hidebound" an incision was made into the thickened tissue. All of the cases except one had been tested electrically. In practically all instances the paralyzed muscles did not react to faradization. The Lewis-Jones condenser has been found of great assistance as it furnishes a numerical equivalent indicating the degree of interruption of conduction through the nerve and the condition of the muscle. The condenser also furnishes important indications as to the site and severity of the lesion. The disappointing feature of the treatment of nerve injuries is the long period required for the completion of the reparative processes, and so far very little information can be given as regards the results of this work, most of the cases having been operated upon after the beginning of August.

4. Gunshot Wounds of Nerves.—Wilfred Trotter states that a large experience is being acquired in the surgery of the peripheral nerves and that while it is too soon to arrive at definite conclusions they might gain something if they could agree upon the general lines of technique that their treatment should follow. The problem of restoration which an injured nerve presents is distinguished by certain peculiarities from all other similar tasks in plastic surgery. 1. The interruption of a nerve leaves a permanent effect in the physiological equipment of the body which cannot be overcome or compensated for by any other mechanism. 2. The restoration of a nerve to its normal anatomical continuity, although an essential preliminary to recovery, is by no means a guarantee of it. The writer classifies his cases in a broad way into (1) intradural nerve injuries, almost entirely injuries of the cauda equina, and (2) peripheral nerve injuries, which may be typical complete lesions of one or more nerve trunks; mixed lesions with complete division of some and incomplete division of other closely adjacent trunks, chiefly seen in the brachial and sacral plexuses, but especially the former; incomplete lesions without pain; incomplete lesions with pain; and pure pressure lesions, as from a prominence of bone or a foreign body. A discussion of the principles of operative treatment leads the writer to two conclusions: 1. Regeneration is dependent upon, and resisted by, the reactions between exposed nerve substance of a divided nerve and the surrounding tissues. Where such reactions cannot occur there is no regeneration, as in the spinal cord; where such reactions can occur regeneration is apt to be resisted by fibrosis and consequently at times to be greatly delayed or incomplete. 2. Regeneration involving a reaction between the nerve and the tissues is apt to lead to an irritation of the former which makes it hypersensitive. In some persons nerve may be divided and equilibrium between the outgrowing fibers and the encapsulating bulbous end be established satisfactorily and painlessly. In others equilibrium is never regained. Fortunately, in the majority of cases the irritating effect of the encapsulating fibrous tissue upon the nerve tends gradually to subside. The application of these principles leads to certain general conclusions. It is obvious that any attempts to secure regeneration of the cauda equina by suture must fail and this has been fully confirmed by the experience of the writer. In peripheral operations, which offer a hope of regeneration, a great deal of care should be given to securing the most exact coaptation possible of the sutured ends by the finest catgut. When the suture is complete the junction should be wrapped in a layer of subcutneous fat which may well be a quarter of an inch thick, and should extend, if possible, two inches on each side of the junction. As far as experience shows us at present the most important points in the technique of nerve resection are free excision, exact coaptation, careful insulation, and perfect asepsis. Muscular relaxation before and after the operation is perhaps equally important.

1. Nervous Affection of the Sixth and the Seventh Decades of Life.—J. Mitchell Clarke says that these decades constitute a period of life which has certain marked characteristics. Many nervous diseases run a long course and we would expect to find that the nervous diseases of this period will be made up of some which began at an earlier age, and of others, fewer in number, whose incidence is contained within it. The diseases of the spinal cord are numerous and important between the ages of 50 and 70 years of age and are largely diffuse lesions of the posterior or lateral columns, mostly degenerative, those formerly grouped as "combined sclerosis." Caries of the spine, hypertrophic cervical pachymeningitis, and internal pachymeningitis, involving a great extent of the cord, and probably of syphilitic origin, are probably very seldom met with after fifty. Tabes dorsalis fairly maintains its frequency in the sixth decade of life, but shows a decided falling off compared with the periods of 30 to 50, and a very marked falling off after 60. The myopathic forms of muscular atrophy do not arise in the periods of life under consideration, but the myelopathic forms are relatively frequent after 50. Dis-

seminated sclerosis, syringomelia, and neuritis usually have their onset at an earlier period of life. Likewise meningitis due to pus-producing organisms becomes uncommon after 50, and tuberculous meningitis in persons over 50 is very exceptional. Cerebral tumors, cerebrospinal syphilis, the neuroses, epilepsy, hysteria, and neurasthenia are uncommon after 50 years of age. Vertigo is occasionally the chief symptom in an attack of late epilepsy and is one of the common and most distressing of the nervous affections of later life. Neuralgias due to gout, arteriosclerosis, various cachexias, and the presenile disturbances of nutrition are not uncommon. Paralysis agitans, though not a very common disease, is preeminently one of the period of life between 50 and 70 years. The writer concludes that a review of the nervous affections of the sixth and seventh decades of life shows that many nervous diseases do not occur at all, others are modified in their symptoms, and a few especially affect this time of life. Except for the nervous diseases dependent upon vascular disease this period of life comes out more favorably in comparison with other ages than one would perhaps have expected. Cerebral hemorrhage, thrombosis, and hemiplegia afford a very large proportion of the sufferers between 50 and 70 from all the diseases considered in this article. Further it has been shown that disease of the arteries materially affects the course of most of the nervous affections at this period. It is possible that the affections mentioned as characteristic of this period of life owe their origin to that process of premature senescence known as abiotrophy, and that this pathological process may occur at any age.

4. **Magnetic Properties of German Bullets.**—Sinclair White writes that it is not generally known that German rifle bullets are strongly attracted by an ordinary magnet, whereas the English bullet is quite devoid of this quality. The difference is due to the composition of the casings. The English bullet has a casing of 80 per cent. copper and 20 per cent. nickel, and this alloy in the above proportions is non-magnetic. The casing of the German bullet is a steel containing 3.36 per cent. nickel and low in carbon. With the highly successful methods of localizing war missiles in the body by the *x*-ray magnetic tests are no longer of any value for this purpose, but the magnetic attraction possessed by the German bullet may under certain circumstances be utilized to assist in its removal from the body.

Whooping Cough.—Lange, a Danish physician, seeks to reduce this subject to aphorisms. We do not know just how the disease is contracted, nor does the author recognize the accused germ as the proved cause. We know the disease is contagious, and that it assumes an epidemic incidence. We know that it readily falls into the group of diseases which attack children and comprises measles, scarlatina, and diphtheria. That is, it begins locally and becomes generalized. But its local symptoms are so violent that a systemic infection seems hardly existent. Nevertheless, the latter is indicated by the three symptoms, leucocytosis, febrile reaction, and conferred immunity. Moreover, there is a marked nervous component, as shown by the convulsive nature of the paroxysms which appear to have an aura, actual convulsions in very young children, glottic spasm, and vomiting. The majority of practitioners undervalue this nervous component which the author almost regards as the solution of the riddle. The late, lamented Jochmann, a great authority on infectious diseases, was puzzled to find the influenza bacillus in the sputum of pertussis subjects and indeed in all stages. We know since the great influenza pandemic of 1889 that this disease can appear as a gastroenteritis and also in a nervous form. But influenza was hardly known to moderns before that pandemic. We now regard it as the most protean of all diseases. Whooping cough we know of old. Most of us have had it and obtained some immunity, at least as regards a bronchial infection. Let us distinguish between local and general symptoms. In whooping cough a child perhaps in full health has a tremendous seizure, which is almost enough to destroy it. A few moments later, apparently well, it has resumed its play and with no fear of another paroxysm. What is the efficient cause of such distressing phenomena? No matter how severe, how intense a laryngitis, tracheitis, bronchitis due to another cause no paroxysms like those of pertussis ever develop. This gives specificity to the disease. Can the Bordet-Gengou bacillus produce it and produce it alone? The disease is a so-called children's malady, although well known in adults. But while the former swallow the sputum, the latter expectorate. The amount of secretion is always small for a catarrh of the breathing tubes. The presence of ordinary influenza bacilli could hardly account for these paroxysms; hence we must investigate from this viewpoint the alleged specific cause. Thus far the proof that this is the Bordet-Gengou bacillus is lacking. Influenza is a disease of adults. When children contract it it is relatively simple in type. The author appears to reach the conclusion that the influenza bacillus found by Jochmann in the sputum of pertussis may be the true cause of the latter. He quite overlooks the fact that several distinct microorganisms can cause a typical influenza synchrome—the pneumococcus for example. In summing up he mentions the specific character of whooping cough, its catarrhal and convulsive stages, its nervous component—the latter a central irritability. Similarly in influenza the nerve centers may suffer, but no influenza cough ever has the violence seen in pertussis. No attempts are made in the direction of a umcistic conception, yet the author evidently regards the two affections as belonging to one group.

Anaerobe Sepsis.—Pribram uses this term for the severest forms of gas sepsis, characterized by a special type and fulminating onset. That obligate anaerobes in virulent condition can circulate in blood which contains oxygen, and is propelled by a properly acting heart will seem strange to some readers. Let us take the lesion known as subfascial phlegmon, in which the bacteria find their most approved culture bed in muscle tissue. The gas formed here is CO_2 from muscle glycogen, and is diffused so rapidly through all the neighboring muscle tissue that it ceases soon to possess any surgical interest. The entire musculature of the thigh, buttocks and small of the back. In the upper extremity the same kind of invasion is seen—invasion which is determined purely by muscle anatomy. Nevertheless, *when phlegmons form*, cure is possible, even though amputation cannot avail. A free incision may show streptococci and sporing anaerobes in association; but in a day or two later only the streptococci are seen in pure culture. The trouble is with those diffuse infiltrations of deep seated muscle, because the anaerobes then enter the blood and cause their peculiar type of sepsis. In such cases there is apparently no mixture of infection, no pyogenic cocci to enter the blood. So rapidly do the anaerobes act that

they infect the blood long before any of the aerobic causes of sepsis could arrive at the same destination. The first results of anaerobes in the blood is unusual thrombosis of the finer blood vessels. Division of such muscles is not followed by escape even of a drop of blood. The infected tissues must soon perish and then the anaerobes find their most welcome culture bed. We now see gas gangrene. In theory as in all gangrene extirpation involves cutting into tissues that bleed. Mere incisions and instillation of superoxides and oxygen have never rendered service at the author's hands. The swollen, algid tissues, however, may cause at first but little systemic reaction; but sooner or later dyspepsia sets in. The blood pressure drops and death occurs suddenly from cardiac failure. Before death the author has been able to cultivate the anaerobes from the blood. Death he attributes to acidosis, due to CO_2 produced from the muscles. The usual foamy appearance of the blood and pulpy organs is noted. The color of the liver is exactly that of cigar ashes. In anaerobe sepsis icterus may be a prominent symptom or it may be absent altogether. The anaerobes show considerable variety in size and shape, and the author makes no attempt to identify them.

Campaigns Against Flies and Mosquitos.—Seelhorst gives his experience with the fly plague in a military hospital. The first thing to do is to locate the breeding places. These should be screened off, while waste water should be drained away. Foods should be kept in closed vessels, chests, drawers, etc. Pits for dejecta can be made flyproof. Portable outfits should have all seams tightly calked, and vaults for the feces should be dug deep. Measures directed against the flies themselves are based largely on proper ventilation of rooms. In the daytime open windows and doors, especially with southern exposure, attract flies, but at dusk they tend to escape. In the daytime doors and windows must be screened. In regard to mosquitos Halberkann discusses tincture of pyrethrum, the powerful odor of which is thought to repel the insects. He himself believes they are attracted by it, and finds that none of the essential oils reputed as protecting against the mosquitos can make good on a large scale. Volatile oils cannot block their respiratory organs, and fluids offer the best hope. A mixture of tincture of pyrethrum, soap tincture, and glycerin is used by travelers.

Deutsche medizinische Wochenschrift.

October 7, 1915.

Vitamines and Accessory Nutrient Substances.—Two groups of phenomena of the physiology and pathology of nutrition are connected with the absence of certain substances in the diet. The first refers to the development of certain diseases like beriberi, scorbutus, and pellagra, either from the absence of some unknown substances essential to life, or from toxic substances due to imperfect metabolism conditioned by such absence. The second has to do with defects in inorganic articles of diet, so called mineral starvation, not necessarily due to absence from the diet of mineral matter but rather to inability to fix it in the tissues. Thus the type of the first class of cases would be beriberi, as due to a diet of polished rice, and of the other class rickets would be the chief representative. A material has been obtained from rice and yeast which can cure experimental polyneuritis in fowls and pigeons; and it has been assumed by Funk and others that we have here a substance essential to life. More recent efforts, however, tend to show that the metabolism of polished rice gives rise to toxic byproducts, so that the polyneuritis of beriberi is toxigenic like polyneuritis in general. However, the deficiency and toxic theories need not exclude each other, and in all forms of inanition, partial or total, there appears to be a toxic component. Infantile scurvy or Barlow's disease can be produced by a boiled milk diet, by certain cereals, flours, etc., when the child subsists entirely upon them. In recent years the laws of mineral metabolism are being studied. It is now believed that in deficiency diseases the missing substances are not themselvese molecular but enter into the formation of large molecules of protein substances as atoms or radicles. In other words they form a part in the regular syntheses of metabolism. We know of course that heterologous animal and plant albumin of the diet must be broken up by digestion and synthetized into homologous protein which must again be disintegrated before it can be eliminated from the organism. The minimum protein requirement of which we hear so much must of course be biologically sufficient. Recent research appears to have shown that neither meat proteins or casein have the theoretic value attributed to them. In other words when we reckon that we are getting 100 gm. of utilizable protein in this manner the real figure is much nearer 70 gm. In this respect these proteins are inferior to those of potatoes and rice, although much above those of wheat flour and maize. Highest of all in biological value is the protein of vegetables like cauliflower and fruits like cherries. Bread is richer in utilizable protein than the flour from which it is made, because of the added protein in the yeast. In regard to the protein molecule, the simplest of them do not have an exclusive nitrogen ring as a nucleus, the N atoms being associated with other elements. Upon certain kinds of nitrogenous fodder animals cannot maintain N-equilibrium; however, after certain mineral additions to the diet, the approach to N-equilibrium is considerable. The more variety in diet, the greater the possibilities of utilization—hence, to any nitrogenous article we should add simple carbohydrates, fats, lipoids, vegetable extracts, etc., in order that higher syntheses be favored. Whenever any class of foods is left out of the diet we have to think of a possible damage to nutrition.

Universal Pigmentation.—J. A. Nixon reports a case of this condition in a man, aged 33 years, in whom spontaneous universal pigmentation had developed during the last six years, until, at the time of the report the whole body was of a dark brown tint, resembling the skin of a native of India. The man dated his condition from an attack of dyspepsia, with neurasthenic symptoms, six years ago. Immediately afterwards he noticed a gradual bronzing of the skin which was exposed to sunlight; and exposure to the sun always increased the intensity of the pigmentation. During the winter, or whenever he stayed indoors, there was a slight fading. There was also staining of the mucous membrane of the cheeks and tongue. At present there were no other signs of disease about him; no syncopal attacks or asthenia, and no loss of weight. The exhibitor associated the condition with an attack of acute dyspepsia. Possibly there was an inflammatory lesion which involved the suprarenals and the solar plexus.—*Proceedings of the Royal Society of Medicine.*

Origin of Blood Platelets.—Dimond believes that the blood platelets are derived from azurophile bodies inside of the red blood cells. He has observed one of these bodies gradually occupying a protrusion of the envelope of a red blood cell; and later a flagellum from the body passing through the envelope. After a few minutes the envelope of the red blood cell seems to be retracted, leaving the platelet adherent to the outer surface of the red blood cell.—*Journal of Pathology and Bacteriology.*

Insurance Medicine.

Monetary Compensation for Disability Following Traumatism.—In a discussion of a paper relating to this subject and presented by Sir Thomas Oliver before the Assurance Medical Society, Dr. F. Parkes Weber showed how easy a matter it was to overlook fracture of the ribs in cases of pneumonia, pleurisy, and rapidly developing tuberculosis following an accident. In these cases where the symptoms show marked contusion of the lung tissue an *x*-ray examination should be made, and it is a safe precaution in any accident where the chest is involved. He cites his own case, when he had the misfortune to fall heavily on to a projecting bar. There was great pain in the chest afterward, but he was assured by an excellent surgeon that none of his ribs had been fractured. After he had completely recovered a Röntgen-ray photograph showed decided formation of callus, proving that one of his ribs really had been fractured. Recovery in such cases would be quicker perhaps if injured persons did not know that their ribs were broken.

With regard to tuberculosis of suspected traumatic origin, he points out that in cases which can be readily followed, and where there is no complicating question of damages, there is often the greatest difficulty in deciding the importance of the traumatic element, and how much effect it may have on the case.

For instance, one case, that of a little boy who showed signs of tuberculous meningitis after treatment for tuberculous bone-disease by scraping. This patient died of the tuberculous meningitis, and the necropsy showed, besides the meningitis, a caseous nodule in one lung, a caseous bronchial gland, and caseous nodules in the cerebellum. The boy, previously to the scraping, had just had measles, and measles combined with caseous bronchial glands is a well-known reputed source of tuberculous meningitis; therefore there is no justification in assuming that the operation of scraping had anything to do with the onset of fatal meningeal tuberculosis. He also suggests that the local tuberculous affections which sometimes develop after contusional injuries at the site of the traumatism may be compared to the local gummatous lesions which occasionally develop under the same conditions in apparently healthy but syphilitic subjects.

In regard to the special risks which, in the future, a private employer of labor will lay himself open to if he employs workmen without having them previously medically examined—especially those who, while they may appear healthy are syphilitic subjects or have some form of quiescent tuberculosis—he suggests that in a well-ordered State private employers should employ only those men who are medically certified as first-class, and that all second-class lives should, after medical examination, be left to the Government for the Government to employ, as suitably as possible, and for the Government to pay, as well as possible.

Dr. T. D. Lister considers that in traumatic phthisis probably most people have a latent focus of tubercle and a contusion of the lung may occur without fracture. This is exemplified in the case of pugilists who receive enormous blows upon the chest and injuries, yet few of them develop tuberculosis, due to the fact that they are absolutely healthy men. Perhaps the most acute injury the lung can suffer is the inhalation of noxious and irritating vapors, yet in a statistical investigation he was unable to find that the workers in chemical factories suffered more from tuberculosis than others. They had bronchitis, but they seemed to become attuned to the vapors they were compelled to inhale.

Dr. A. T. Davies presented the fact that pathology has accumulated enormous evidence to show that tubercle is universal. "The greater our civilization, the greater our syphilisation," and he also thinks that it might be truly said, "The greater our civilization, the greater our tuberculization," and therefore he would be prepared to accept as an axiom that if we have a case of tuberculosis occurring in trauma it is fair to conclude that there has been excited in that case an old tubercular lesion. This falls in with the pathology universally held today.

Dr. R. A. Young cited two or three cases observed in soldiers returning from the war who had been severely shaken by high explosive shells, one of them having been knocked over twice. This man had a very severe hemoptysis and a very active tuberculosis afterward.

Sir Thomas Oliver in the summation of the discussion announced that it was pretty well agreed that it is practically impossible for an injury to the chest to develop disease such as tuberculosis, which is so purely microbic; therefore, the germs of the disease must be in the body at the time. Whether there is that requisite peculiarity of soil in which the disease alone can develop one cannot say, but there is a lowered resistance after an injury, which he considers is largely an explanation of the traumatic tuberculosis. Pugilists are healthy men and do not develop tuberculosis, but another side of the question is presented in the men who work among the barges and boats on the River Loire. The labor of pushing the boats and rowing, the pressure of the rudder upon the chest, must have some harmful influence, for many of the men die from phthisis, and in larger proportion than men following other occupations.

With regard to the influence of noxious fumes on the lungs, while chemical workers do not suffer from phthisis to any great extent, they develop emphysema and bronchitis. The lungs of a man who has been exposed to the nitric fumes practically become burnt; there is intense congestion of the lungs, with engorgement of blood. These men nearly always die in the acute stage of the illness, so it is impossible to know to what extent the lesion would be followed by tuberculosis.

Accident Insurance: "Voluntary" and "Accidental."—Action was brought on a policy insuring against death, through external, violent, and accidental means, but providing that the insurer assumed no liability for death from the voluntary or involuntary taking of poison. The deceased's death was caused by medicine given him by a doctor, which contained strychnine. It was held that the insurance company was not liable, since, while the taking of the poison as distinguished from the taking of the medicine was unintentional, a thing is not "accidental" which is intentional and voluntarily done, and the word "voluntary" infers an act done with volition, knowledge, and intent, while "involuntary" is an antonym of "voluntary," and applies to an act done without volition and intention.—Riley v. Interstate Business Men's Acc. Assn., Iowa Supreme Court, 152 N. W. 617.

Book Reviews.

PHYSICAL DIAGNOSIS. By RICHARD C. CABOT, M.D., Assistant Professor of Medicine in Harvard University, Chief of the West Medical Service at the Massachusetts General Hospital. Sixth edition, revised and enlarged, with six plates and 268 figures in the text. Price, $3.25. New York: William Wood & Co., 1915.

THIS book has been entirely rewritten or revised in the parts pertaining to the diseases of the heart and to the diseases of the lungs. It is an account of the diagnostic methods of competent practitioners. It is unique in that the author limits the description of methods to those with which he is personally familiar. There are a few typographical errors and in some instances the references in the text to the illustrations are incorrect. There are also some instances of confusion and inconsistency in the text. For example, on page 194 the author stresses the point that violent exertion never produces acute dilatation in the previously sound heart; but on page 199 he states that great muscular fatigue, such as is produced by a hard boat race, may result in a temporary relaxation of the mitral sphincter or of the papillary muscles sufficient to allow regurgitation. It is true that he uses different words but the latter condition is what most clinicians understand as acute dilatation. On page 175 in giving a summary of the causes of diminution in the intensity of the aortic second sound the author mentions mitral disease alone in explanation of the general statement that the sound is diminished whenever the blood stream, thrown into the aorta by the left ventricle, is abnormally small; yet on page 222 absence or great enfeeblement of the aortic second sound is enumerated as one of the four cardinal signs of aortic stenosis. The inaccuracies in this book, however, are few and slight and do not detract from the value of the work. The criticism is made solely to emphasize the need of meticulous accuracy in books of this character. In general the author's style is particularly welcome because of his clearness and his use of the simple hospital or clinical vernacular rather than more heavy, technical language. For this reason it is a very readable book. It is well arranged for quick and ready reference. For the practitioner, for whom it is primarily intended, it is the best work we have on physical diagnosis.

CANCER: ITS STUDY AND PREVENTION. By HOWARD CANNING TAYLOR, M.D., Gynecologist to the Roosevelt Hospital, New York; Professor of Clinical Gynecology, Columbia University; Member of the American Gynecological Society, American College of Surgeons, American Society for the Control of Cancer, American Medical Association, New York Obstetrical Society, etc.; 12mo, 332 pages. Price, $2.50 net. Philadelphia and New York: Lea & Febiger, 1915.

WHEN one thinks of the enormous mass of literature devoted to the subject of cancer, one instinctively questions the need for another book on this subject which does not profess to offer any new theories as to the causation of cancer or present anything revolutionary in the way of treatment; but even the most casual examination of Taylor's work is enough to prove the fallacy of such an opinion. From an initial hostile attitude the reader soon becomes appreciative and is gradually impressed with the fact that Taylor's contribution furnishes a most thorough but remarkably concise and valuable review of the cancer problem in all its various aspects.

The word "cancer" is used in the title in its broad sense, covering all malignant tumors, hence in the body of the book sarcomata are discussed as well as the various types of carcinomata. The author has so arranged his material, statistical and otherwise, as to give one a good general grasp of the subject and to make the facts as to the type, relative frequency, clinical course, symptoms and diagnosis of cancer as it affects the various tissues and individual organs of the body easily accessible. There is no verbosity, there are no flights of rhetoric—merely a plain statement of the essentials together with the iteration and reiteration of one point that is, unfortunately, only too true, namely, that a very large percentage of the patients with cancer come or are sent to the surgeon too late for successful treatment. It is to awaken the profession at large to this state of affairs, to present the data in such a way as to stimulate interest and render easier the early recognition of cancerous involvement, and to make the general practitioner realize his responsibility if he is the one that is to blame for the patient's procrastination in seeking surgical relief, that Taylor has given his time and brains in the preparation of this work.

In the light of what we have already said extended review is unnecessary. Everybody, general practitioner and surgeon alike, should read this book, ponder over some of the statements it contains, and profit by a realization of what delay in the diagnosis and early treatment of cancer means to his patients.

DIARRHEAL, INFLAMMATORY, OBSTRUCTIVE, AND PARASITIC DISEASES OF THE GASTRO-INTESTINAL TRACT. By SAMUEL GOODWIN GANT, M.D., LL.D.; Professor of Diseases of the Colon, Sigmoid Flexure, Rectum, and Anus at the New York Post-Graduate Medical School and Hospital. Illustrated. Price, $7.50 net. Philadelphia and London: W. B. Saunders Company, 1915.

THIS volume presents a comprehensive exposition of the etiology, pathology, symptoms, diagnosis, and treatment of acute and chronic diarrhea and allied conditions. The numerous systemic and local diseases in which diarrhea is a prominent symptom are discussed in satisfying detail. The wording of the title of this book is not a particularly happy one: the terms "diarrheal," "inflammatory," "obstructive," and "parasitic" overlap one another in their connotation; and the large group of obstructive diseases comprised under constipation are not dealt with in this volume. Considerable attention is paid to the irrigation and to the surgical treatment of diarrheal conditions, the operations of enterocecostomy, appendicostomy, appendicocecostomy and appendico-enterocecostomy being described in detail. The illustrations are numerous and of a high order of merit. Among the many other excellent features of this book is the extensive formulary of prescriptions suitable for different types of diarrhea and at different age-periods.

INTERNATIONAL CLINICS, a Quarterly of Illustrated Clinical Lectures and Especially Prepared Original Articles on Treatment, Medicine, Surgery, etc. Edited by HENRY W. CATTELL, A.M., M.D., Volume III, Twenty-fifth Series, 1915. Price, $2.00. Philadelphia and London. J. B. Lippincott Company.

IN this issue of the Clinics there are twenty-five articles on diagnosis and treatment, pediatrics, surgery, and borderland medicine. The most valuable and comprehensive is the one on the Treatment of Fractures of the Lower End of the Radius by J. B. Roberts. Two others are of very great interest, one on Medieval Medicine by C. G. Cumston of Geneva and the other on War Experiences by L. Rahm of Zurich. The remainder of the volume does not come up to the standard which we have grown to demand of this publication. There is nothing in them which is bad but they approach that dead level of mediocrity which is sometimes worse.

THE PRACTITIONER'S ENCYCLOPEDIA OF MEDICAL TREATMENT. Part I., Methods of Treatment. Part II., Agents in Treatment. Edited by W. LANGDON BROWN, M.D., F.R.C.P., Assistant Physician to St. Bartholomew's Hospital and Physician to the Metropolitan Hospital, and J. KEOGH MURPHY, M.C., F.R.C.S., Surgeon to the Miller General Hospital for South East London and to Paddington Green Children's Hospital; with an introduction by Sir THOMAS CLIFFORD ALLBUTT, K.C.B., M.D., F.R.C. London: Henry Frowde and Hodder and Stoughton, 1915.

THIS encyclopedia, as its name denotes, is really an encyclopedia and is full to repletion with the most modern methods of treatment and the agents now employed in treatment. However, although full of information, the fault of redundancy is adroitly avoided and the book is commendably concise in diction and always to the point. Sir Clifford Allbutt supplies a preface, which, charming from the literary aspect, draws attention to the fact that while empirical medicine is passing away, its decease is not yet; it lingers, and many a year will come and go before the scientific therapeutist becomes independent of the empiric.

The work before us reflects much credit on the joint authors and will serve as a valuable *vade mecum* to the busy practitioner who desires to be abreast of, or to refresh his memory with regard to, the latest methods of treatment and the agents used for this purpose.

Society Reports.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held October 25, 1915.

THE PRESIDENT, DR. HOWARD LILIENTHAL, IN THE CHAIR.

Second Report on Connellan-King Diplococci Infections of the Tonsils.—Dr. JAMES J. KING reviewed the histories of a number of cases which he had presented on a former occasion. (See page 958.)

Dr. JOHN J. CONNELLAN said that about two years ago, following the publication of the work by Smith and Bass on "Entameba of the Mouth," Dr. Hasbrouck, who made a specialty of teeth extraction, asked him if he would make bacteriological examinations of the cavities following extraction. The areas around the tooth before extraction were sterilized by means of tincture of iodine while the patient was under gas. All precautions possible were used in getting at the material following extraction. The warming stage methods for entameba were used with negative results. Plate cultures without exception showed almost pure cultures of large, yellowish tinged irregular colonies, with a tendency to subsurface development. Some of these cavities showed the presence of pus. Having in mind that many types of organisms generated toxins of questionable character and amounts, he was led to ask Dr. King if he would look into other parts of the mouth and throat for this organism. The first case, that from the deep crypts of the tonsils, showed a pure culture of this organism. He suggested a vaccine starting with 50,000,000 per cubic centimeter. The organism was a small Gram negative diplococcus on veal agar. On plain agar it had more the tendency to a coccus formation. It did not ferment any of the Hiss sugar serums, but formed acid and coagulation. On a litmus calcium carbonate lactose agar sugar, the field resembled somewhat that of the colon bacilli. On blood plates none of the characteristics of the streptococci group were present. Milk tubes cultures resulted in coagulation and acid without whey. Cultures taken from the ear and nasal tracts in these cases showed the absence of this organism.

Dr. PERCY W. ROBERTS said he had had the opportunity of using the vaccines in old chronic cases of osteoarthritis. The cases described by Dr. King were quite different from those with which he had been dealing. In twenty-five or thirty cases many of the cultures taken from the throat were positive. He gave the vaccines in doses of 0.1 or 0.2 c.m., starting by giving them every fourth day and then every second day. He thought these vaccines had been of value, although one should bear in mind that the class of cases he had treated were the long standing ones in which one did not look for very brilliant results, but was glad to avail himself of anything that promised any help whatever. There were three or four cases in which the clinical results were very striking. He stated that his private patients treated with autogenous vaccines had all shown a diminution of pain and showed a distinct change for the better. He felt that in the use of the autogenous vaccines Dr. King had found something in the way of a weapon with which to combat osteoarthritis.

Dr. W. P. CONAWAY of Atlantic City gave his personal testimony as to the efficacy of autogenous vaccines in conditions due to the Connellan-King diplococcus.

Dr. JAMES J. KING said that in taking the cultures he tried to get them from the deep crypts. He usually took cultures before removing the tonsil so that if any complication arose he would have an autogenous vaccine with which to combat it.

Tracheloplastic Methods and Results: A Clinical Study Based Upon the Physiology of the Mesometrium—Dr. ARNOLD STURMDORF said it was not the tear in the cervix, but the induced complications which brought the patient to the operating table. The dominating fundamental factor that established the morbidity of a cervical lesion was the incidence of infection. The functional integrity of any organ depended upon the maintenance of a uniformly circulatory equilibrium, and this was particularly true of the uterus. In the uterus, as elsewhere, every infection incited the greatest reaction in its lymphatic elements. The arrangement of the lymphatics made it clear how an infectious process of the cervix, inducing an ascending intramuscular lymphangitis, might splint and immobilize the elementary bundles by plastic infiltration of their sheaths. It was an axiomatic surgical principle in the control of any ascending lymphangitis to direct their therapeutic aim at the primary infectious focus, and hence the indications for and limitatons of trachelorrhaphy or cervix amputation must be governed by their relative efficiency in the elimination of the infectious cervical focus and the restoration of normal uterine functions. Simple trachelorrhaphy should find its cardinal and practically its only sphere early in the puerperium, during which so-called immediate or intermediate operation presented an effort of the highest prophylactic potency. Dr. Sturmdorf called attention to the disregard of the physiological and textural features of the cervical elements. The peripheral muscle fibers traversing the greater circumferential area were much longer than the central fibers that entwined the uterine cavity and hence on ablating the cervix in the usual manner all the muscle stumps were made to terminate at the same level, the longer peripheral fibers contracting to a higher plane than the shorter central fibers; this must tend to pull the vaginal and endometrial margin of the stump asunder, and furthermore the extreme friability of the endometrial edge rendered its suture purely transitory. These exposed stump surfaces healed by granulation and some never healed. Realizing some of the surgical shortcomings, many gynecologists had devised procedures to overcome them. Dr. Sturmdorf stated that after an extensive critical test covering a period of over three years he wished to present a procedure which he had originated and which fulfilled the physiological demands, met the pathological indications and obviated the shortcomings enumerated. This operation he described with the aid of lantern slides. It consisted briefly of outlining and free mobilization of an ample circular flap from the vaginal sheath of the cervix; complete excision of the entire cervical mucosa to the internal os, with preservation of its peripheral muscular envelope, sutural coaptation of the vaginal cuff of the denuded cavity. The dilator and the curette were absolutely excluded from the armamentarium for this operation. The object of the first step was the formation of an ample motile cuff of vaginal mucosa; with this object in view the incision was carried around the cervix closely skirting the demarcation between its healthy vaginal sheath and the diseased mucosa running parallel to the indented line at the lacerated points. The pouting everted cervical mucosa was circumscribed and cored out of its muscular bed as a hollow cone leaving a raw funnel-shaped cavity. The loose vaginal cuff was trimmed to serve as an accurate lining to the interior of the muscular funnel. Its retention was secured by beginning with the anterior segment of the circular flap; a long strand of heavy silkworm gut was passed on its vaginal surface, transversely through the free border of its central tip, one-eighth of an inch from the edge, like a mattrass suture, the entrance and exit of the strand embracing a quarter inch of tissue. The right free end of the suture was next carried into the cervical cavity at a point just above the internal os where, piercing all the tissues in a direction forward, upward and to the right it emerged from the vaginal surface at the base of the flap. The left free suture end was passed in the same manner forward, upward and to the left, so that the two free ends diverging in their transit reappeared on the surface of the anterior vaginal fornix, about one-quarter inch apart. The suture course for the posterior flap segment ran parallel to the above, but in a posterior direction, its free ends emerging on the surface of the posterior vaginal fornix. So by tightening the sutures the flap segments were drawn into the cervix, lining the whole cavity with vaginal mucosa. In directing the suture through the cervical tissues, a double curved Peasely needle should be substituted for the round needle, after engaging the tips of the flaps in the first stitch. A narrow strip of iodoform gauze introduced with the object of maintaining a flat uniform coaptation of all raw surfaces finished the operation. This procedure effected the complete elimination of the infectious focus by extirpation of the diseased cervical mucosa, preserved the normal arrangement, contour and functions of the cervical musculature, obviated the mechanical difficulties of the older operations and secured the permanence of accurate sutural evaporation of flap to stump.

Dr. J. RIDDLE GOFFE congratulated the Society on having had the privilege of listening to such a scientific,

original, and altogether admirable paper as that just presented. He stated that Dr. Sturmdorf had arrived at conclusions toward which they had all been drifting for some time, and hence this paper had come at a timely moment when they were prepared to accept it. Dr. Sturmdorf had drawn a picture of the results of destruction of the rhythmic contractions of the uterus and he compared these thythmic contractions to those of the heart; he was quite right in what he said, without these rhythmic contractions the uterus became a dead organ, the rhythmic contractions were its life. Dr. Goffe also agreed with Dr. Sturmdorf in what he said about metritis. They no longer recognized such conditions as chronic endometritis; the conditions formerly designated by this term were now compared to certain conditions preceding or succeeding menstruation. Curettage was also a procedure which was being eliminated, except perhaps for diagnostic purposes in certain cases in which malignancy was suspected and in which it was done for the purpose of obtaining a specimen in order to determine the true condition. Coming to the operation Dr. Goffe said he thought Dr. Sturmdorf had devised as complete and perfect an operation as it was possible to do; it preserved the peri-cervical and circumferential tissues, with their muscular fibers, in the proper proportional lengths of the various fascia, which was most important in retaining and restoring the rhythmical contractions and the health of the uterus. If one restored these functions he would get rid of infection in the lymphatics, since with the restoration of the contractions one would get pressure on the lymphatics which would gradually get rid of the infection. Another method of setting up contraction was that of packing the uterus with gauze. Dr. Goffe said that while he had not performed this operation himself, he had seen Dr. Sturmdorf perform it. The flaps were easy of adjustment and he would put the operation into practice himself at the earliest opportunity.

Dr. Albert M. Judd of Brooklyn agreed with Dr. Sturmdorf that changes in their method of attacking the cervix were necessary. This conclusion had been reached by following up cases after the operation of trachelorrhaphy had been performed and finding that frequently cystic degeneration had taken place. Dr. Sturmdorf made reference to the fallacy that a narrow cervical canal was responsible for sterility. In experiments carried out on monkeys it had been found that twelve drops of blood passed in every twenty-four hours during menstruation. From such evidence it seemed that they would have to give up the idea that stenosis of the cervical canal was a cause of dysmenorrhea, but, of course, there were clots from prolonged congestion and they would have to be taken into consideration. As to the curette, Dr. Judd said he felt at times that it should be relegated to oblivion or at least kept only for museum purposes. The rapidity of the operation that Dr. Sturmdorf had presented was one of its greatest advantages. He had performed the operation himself fifteen times and this had taught him that Dr. Sturmdorf's method was extremely practical. After the operation there was no granulating surface, and the method used in suturing gave results that were absolutely perfect save in one or two details. It seemed to him that with two sutures there was more liability to hemorrhage than if more sutures were used. The Peaseley needle also gave him some trouble since it did not seem to be sufficiently stiff when it passed down through the internal os, so he used one modeled on the Carsten plan by one of his associates, Dr. Wessenberg. He had also found that there was danger of entering the posterior cul-de-sac in making the posterior flap. In suturing, Dr. Judd said he used chromic and not silkworm gut, as he had not as yet the courage to use the plain gut which he used in all his other work. In doing the Emmet-Baldwin operation it was almost impossible to remove the sutures, and the chromic gut had an advantage in this respect as it did not require removal.

Dr. Emil Schwarz said that they had found a penetrating lymphangitis with dense submucous infiltration only in three out of a large number of cases. One case showed also a distinct lymphangitis of the corpus myometrium. In order to prove the presence of an ascending lymphangitis in those cases in which a submucous infiltration of the cervix was present one had to section the entire uterus. Even the presence of scars in the cervix was difficult to prove, so that the technical difficulties accounted primarily for the fact that ascending lymphangitis had been demonstrated in only a few cases.

Dr. Samuel W. Bandler said he must confess to a certain degree of surprise if any claim of originality or novelty were given to the surgical procedure just described. He said he doubted if, during the last twelve years, he had done more than three or four trachelorrhaphies, but he had done dozens of amputations of the cervix in the manner just described. The writer of the paper made no distinction between laceration, octropion, and erosion. An ectropion simply meant that the mucous membrane of the cervix was everted after a laceration. It was often associated with chronic inflammation and an inflammation of this sort frequently existed when the cervix was not torn or injured. An erosion was an entirely different thing from an ectropion, and was almost never present without chronic catarrh of the cervix. If a laceration was a slight one and there was no catarrh, there was no indication for doing any repair to the cervix; if, on the other hand, the laceration was a deep one, and if the infection of the existing ectropion was marked, or there was chronic incurable cervical catarrh, with hypertrophy of the cervix, then Dr. Bandler said he amputated the cervix. During all these years he had been amputating the cervix in the following way: An incision was made around the cervix through the vaginal mucosa and this was pushed back by the aid of the finger covered with gauze, posteriorly, anteriorly, and laterally, so that the cervix was literally skinned out of its vaginal covering. Then as much of the cervix as was desired was cut off in a transverse fashion. This left a vaginal flap which projected out over the raw lower end of the uterus, and it was easy, with four or eight stitches which were passed through the cervical canal and through the edges of the vaginal flap, to cover the cervix thoroughly and perfectly. Any one who examined one of these cervices several weeks after amputation could not tell by sense of touch alone whether the cervix had ever been amputated or not. In the drawings that were presented the condition was simply that of erosion and there was little if any laceration. Oftentimes there was a deep laceration on one side or the other, and one must then make a wide circumcision on the vaginal mucous membrane and a much higher amputation of the cervix. When a chronic cervical catarrh and inflammation was present, there was bound to be a corresponding upward extension, in most cases, into the uterine lining. It was from this uterine lining that an extension of the inflammation passed out into the structure onto the uterine fundus iself. The upward extension from a cervical catarrh, with or without erosion, ectropion, or laceration through the structure of the cervix into the musculature of the fundus itself was a rarity, except in acute cases of infection. Chronic cervical catarrh did not tend to extend upward through the muscles structure of the cervix into the uterus. It tended to spread out into the radiating lymphatics, that was, into the ligaments around the cervix, the uterovesical ligaments, the uterosacral, and the two broad ligaments. When the catarrh and inflammation involved the uterosacral ligaments, sclerosis of these ligaments took place and the uterus was pulled back into the hollow of the sacrum; this was called a retrodisplacement, and had nothing to do with retroflexion or retroversion as such. These two latter conditions were retrodeviations.

Sacral Suspension of the Uterus. — Dr. John Van Doren Young presented this communication. He stated that all corrective surgery must be based on a clear concept of the deformity to be corrected and that a multiplicity of operations for the relief of a deformity indicated a lack of this clear concept. He then reviewed the physics, dynamics, and mechanics of the pelvic organs, calling special attention to the fact that the axis of the uterus formed an acute angle to the axis of the vagina and not a right angle as had usually been taught. The operation which he had devised was directed to the relief of mechanical retroversion, leaving out of consideration all retropositions of the uterus due to post-inflammatory peritoneal contractions, and at the same time recognizing that periadnexal adhesions might complicate a mechanical retroversion, but were never its cause. In a study of a series of 6,134 gynecological cases at St. Luke's Hospital, he had found that 2,238 of these had retropositions of the uterus, and of these 50 per cent. were retroversions. After discussing the etiology and symptomatology of pathological retroversions of the uterus, Dr. Young said his treatment of these cases consisted in general care, instruction in the poise of the body, and local

treatment, before resorting to an operation. The pessary, properly fitted, would give satisfactory results in which the ligaments were not stretched beyond their elastic limits and in which there were no complicating periadnexal adhesions or birth traumas. This treatment should be tried in all cases in which there were contraindication to operation, objection to surgery on the part of the patient, and in all cases in which the retroversion followed immediately after delivery. The operative procedure which had given the writer the best results was as follows: If birth trauma was present, it was first repaired. A long conical, or a lacerated infected cervix, was operated upon by the tracheloplastic method just described, thereby shortening the cervical arm of the uterine lever. The pelvic diaphragm was repaired by the muscular interposition operation. The abdomen was then opened by the Pfannenstiel incision and the uterosacral ligaments shortened by the following procedure: The perisigmoidal adhesions were separated with scissors, while the gut was held in the left hand, allowing the most careful dissection in freeing the sigmoid; the resultant raw surface on the sigmoid and mesosigmoid was repaired by a fine catgut running suture. The round ligament peritoneal trauma was disregarded for the time being, it being cared for by operation on the round ligament after the uterosacral ligaments had been shortened. Peritoneal trauma to the infundibulo-pelvic, or broad ligament, was repaired in the same way. The uterosacral ligaments were cut about three-eighths of their length from the spinal attachment and five-eighths from the fundus of the uterus. Dr. Young described his technique by the aid of lantern slides and stated that he had performed 196 sacral suspensions. In this series there had been no mortality. One patient had since had four deliveries and her pelvic condition was normal. He had had one failure due to perisigmoidal adhesions and one patient was compelled to wear a pessary. He believed that had he recognized the perisigmoidal adhesions in these cases the results would have been different.

Dr. William M. Polk said that when he began to listen to Dr. Young's paper he did not think this subject would be very interesting as it had been so thoroughly threshed over that there seemed little in connection with it to which one could call the attention of the modern gynecologist. However, he found that Dr. Young had taken up a procedure which had been tried thirty or forty years ago and had been abandoned for lack of knowledge of certain anatomical features and for lack of operative technique. Dr. Young seemed to have surmounted the technical difficulties and had thereby evolved a perfect method of shortening the uterosacral ligaments.

Dr. F. C. Holden said he had fairly well-defined ideas on the subject of retrodisplacement of the uterus, none of which were original. The principal prerequisite to success in the cure of this condition was a thorough, painstaking preoperative study of existing physiological, anatomical, and pathological conditions in the individual case. The facts to be considered were the condition of the pelvic floor, presence of rectocele and cystocele, the size, condition, and position of the cervix, and whether there was a long or short invagination of the cervix, and whether the woman was past or in the child-bearing age. When these facts had been ascertained the operation should be fitted to the individual patient and not the individual to the operation. No one operation yet devised or to be devised would ever cure all types of retrodisplacement of the uterus. The woman was to be pitied who was so unfortunate as to fall into the hands of a surgeon who was obsessed with the idea of originality and had devised some operation or modification of some operation to which his name had been added and thought that this operation would cure all types and conditions of retrodisplacement of the uterus. The keynote to success in operations for retrodisplacement was the position in which the cervix was maintained and not so much as to what was done with the fundus. In selected cases the operation described and illustrated by Dr. Young should fulfil this purpose very satisfactorily.

Dr. Jerome M. Lynch called attention to the nerve supply, stating that the hypogastric plexus was the receiving and distributing station for pain and nerve impressions from both the rectum and the generative organs, and that, therefore, if there was a painful lesion in one of these locations the pain might be referred to the other. Hence when one had a patient with symptoms referred to either of these organs a thorough examination should be made to determine the site of the lesion. One frequently saw cases in which such symptoms as diarrhea, constipation, or frequent desire to empty the bowel were the result of uterine retroversion. Or, again, a rectocellulitis might involve the genital organs and simulate uterine disease. Every successful proctologist and gynecologist must have a full knowledge of both fields and be alive to every possible condition that might arise in either and to all possible operative procedures if he was going to overcome the obstacles that presented themselves; otherwise the obstacles would overcome him.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Two Hundred and Seventy-second Regular Meeting, Held Oct. 8, 1915.

Dr. John S. Thacher, President, in the Chair.

Septic Sore Throat. — Dr. Hermann M. Biggs of New York, read this paper (see page 945).

Dr. William H. Park said that Dr. Biggs had covered the subject very thoroughly. There were several points, however, in regard to these epidemics that might be of interest. He remembered one that was entirely of the scarlet-fever type. Ten years ago one had occurred as an outbreak in two boys' military academies, and a girls' school, just before the Christmas holidays. The pupils began to develop sore throat and the authorities of the boys' schools sent the pupils home. In twenty-four hours half the boys developed scarlet fever rash. Physicians considered the cases scarlet fever. It was brought to Dr. Park's attention by the resident physician, and he went up to discover the cause of the epidemic. No day scholars were found to have the disease, but one girl in the boarding school, who was on milk diet, developed a case. It was found, on examination, that one milk dealer, who had such a good reputation that his supply was not equal to the demand for milk, had taken milk from a farm where the sheds were dirty and unventilated. Two days before the epidemic a cow had come in after calving, it had a septic discharge from the vagina and the milk was like a pure laboratory culture of streptococci, there were so many organisms in it. At that time complement fixations were not being done. All of the cases affected developed rashes like scarlet fever, but were not ordinary scarlet fever, clinically. The farmer, his wife, and children were all apparently in good health. There were no deaths in that epidemic. The one Long Island epidemic was of typical sore throat, with no rashes. There were complications of peritonitis. In the cases with rashes, there were different opinions as to whether there were both septic sore throat infection and scarlet fever, and whether both were contagious. Some workers on the bacteriology of the disease, Dr. Park said, were sure that different streptococci made the different cases. He believed the cow first became infected through a person and that the epidemic was caused by the infected cow. It started with acute sore throat in the human, the cow took the same streptococcus, and the cultures from the epidemic showed the same organism. Sometimes the cows had so little the matter with them that it was hard to tell that they were not normal. Excessive care had to be taken that no person with a trace of sore throat should work in a dairy. So far no case had been traced to certified milk of the highest type, but it was quite possible that such might become affected.

Dr. J. W. Brannan said that Dr. Biggs had referred to the rarity of such epidemics. Unfortunately he, Dr. Brannan, had not heard the first part of the paper and did not know whether he mentioned the epidemic of septic sore throat which occurred in Boston and Cambridge some three or four years previously, which was, he thought, the first reported in this country. It was very severe, and many cases were fatal. The outbreak was sudden and difficult to explain, but the infection was finally traced to a dairy farm, which was considered to be one of the best in the country.

Dr. G. E. Brewer asked if in the epidemic that occurred in Eastern Masachusetts, where there were a number of cases in the schools, it was definitely traced to milk.

Dr. Biggs said yes; it was traced to one dairy farm milk; 70 per cent of the patients drank the milk, but the cow was not traced.

Dr. BREWER asked if there was not a type in which the lymphatic infection was very marked. There was an epidemic at Tuxedo, termed "lymphatic fever" which occurred at about the same time. Had that been investigated? At about the same time in New York also there had been a number of cases of sudden acute infection by streptococci of the lymph glands without previous sore throat. He had had no less than three young children to operate upon. The cases were very septic with a temperature of 104° or 105°. The lymph nodes were very edematous and later became necrotic with purulent infiltration. The children were exceedingly ill. The abdominal symptoms had been so prominent that Dr. Richardson believed one to be a case of appendicitis. It had appeared almost typical. Dr. Brewer had had a similar case at Tuxedo, in which he operated. On examination the appendix was found normal, but in the mesentery was a localized abscess. There was evidently a subacute infection from which the lymph nodes were involved. In some cases the abdominal symptoms were the only ones which attracted attention. In the epidemic about Boston there were a number of cases in which the chief involvement appeared to be in the abdominal cavity.

Dr. CHARLES H. PECK said he would like to ask the reader of the paper if these cases showed a bacteriemia. He said he was interested in the report of peritonitis coming as a complication. That was rarely seen in general surgical practice. Some years ago, he had had a patient who developed, at the subsidence of an attack of sore throat, a streptococcus peritonitis. It was recognized at the end of the first week. He believed that the organisms isolated then were identical with those that caused the sore throat, but such cases were rare in his experience.

Dr. M. ALLEN STARR asked if there were any seasonal relation to these epidemics. All seemed to have occurred in February, March and April. Were they common in the spring? He wondered if it were not possible that many isolated cases of septic sore throat had the same origin. He asked if, in view of the fact that many cases had been considered scarlet fever, would it not be possible to find out the relationship of scarlet fever to milk supply in small places. He thought these things were going on all the time, but that they were not recognized. He was not aware of the epidemic spoken of. There was an epidemic of mild sore throat at Mt. Kisco last spring. In cases of this kind, if proper attention were called to it, and the local health officer made sufficient inquiries, it might be found that cases were endemic and not epidemic.

Dr. ARNOLD KNAPP asked if the local health officers were physicians.

Dr. PARK said that some epidemics would never be reported if it were not for the sanitary supervisor.

Dr. JOHN S. THACHER asked if the supervisors went to Albany for instruction, and if so, did they have courses of any kind. He said he thought the relationship between scarlet fever and these septic sore throats was interesting. Were there any cases where the rash was indistinguishable from scarlet fever? He added that there was an idea in the old days that there was a relationship between scarlet fever and puerperal fever. What was the opinion of the meeting on that question?

Dr. CHARLES GIBSON said he remembered a case he reported to the Society of a patient admitted to the medical side of St. Luke's Hospital, which he had diagnosed as acute peritonits in the last stages. He had refused to operate. There was a history of sore throat several days previously. The patient died and a positive blood culture was found. At post mortem there was shown a generalized septicemia. He did not know whether this was due to milk infection. It was after the Boston epidemic.

Dr. BREWER asked Dr. Gibson if his impression was correct that in the abdominal cases, operated on in the Boston epidemic, all the patients died.

Dr. JAMES A. MILLER said that in connecton with the epidemic of scarlet fever at Paul Smith's, they had sixteen or seventeen cases, and there were many cases which were merely bad sore throat, which were not scarlet fever. He wondered whether that frequently happened in other infections. Was that due to streptococcus invasion or not?

Dr. A. A. SMITH said that early in his profession he had visited a great many cases of scarlet fever in children, and nearly always contracted a sore throat when he did so.

Dr. J. C. ROPER asked Dr. Biggs if the enlargement of the lymph glands was general or confined to the cervical glands. He asked Dr. Park if he thought that scarlatina was due to streptococcic infection.

Dr. W. M. POLK asked if there was any possible connection between glanders and this infection. At Tuxedo it was suggested that the infections were similar. He did not know that this was proven. He knew of one case in a friend of his, with sore throat, followed by mesenteric gland inflammation and later peritonitis. The patient had died. A connection had been established between the sore throat and the peritonitis.

Dr. HERMANN BIGGS in reply to the several speakers said that he did not think blood cultures were made; the lymphatic nodes were very much involved in these cases, very much more so than in ordinary sort throat, and extensive cellulitis in the neck was very often marked. As a rule the cases seemed to have occurred from January to June. He thought it probable that isolated cases had the some source. He had been much impressed with the many milk epidemics of various sorts in this State. Their supervision had greatly improved, and he doubted whether any of the three extensive epidemics would have been reported if it had not been for the supervisors. Scarlet fever, diphthera and typhoid epidemics had occurred and he presumed had been occurring for years, without being reported. They escaped report unless they occurred in a large city. In New York City, unless the epidemic assumed very large proportions, it would be hard to trace it. Whenever anything occurred in small places to direct attention to the fact, they had tried to find the connection between scarlet fever and the milk supply. Where a group of cases occurred they were investigated immediately. Now, under the State sanitary code, any infectious disease occurring at a dairy had to be immediately reported. They had had nearly 250 such reports the past year. Very little care was formerly taken about illness on an isolated dairy farm, and very many cases could start from such a focus of infection. In the country health officers had been making much more careful studies. Conditions in the State were rapidly improving, as reported by the sanitary supervisors. A year ago these men were comparatively untrained and their work had improved enormously in a year. He said that the local health officers were paid only 10 cents per capita in the country districts, and it was hard to get even this; if more were paid they could get better men and better work. The supervisors were under the direction of the division of communicable diseases. Many of them were men trained in health work in some of the larger cities. They worked for ten days in the laboratories under the direction of Dr. Wadsworth and then went to Cornell for a short course of instruction in dairy inspection. Cases of scarlet fever occurred often at the same time as septic sore throat, but without rash; that had occurred in scarlet epidemic. At Poughkeepsie a great proportion of the cases were scarlet fever and many more cases were simply sore throat. Attendants in scarlet fever hospitals contracted scarlet fever frequently, but rarely had sore throats without the other symptoms.

Dr. PARK asked if the meeting knew about the regulations for pasteurization. They required thirty minutes. It had been proved, by introduction of coloring matter into the milk, that in a shorter time some of the milk did not get pasteurized. In Baltimore three minutes was not found sufficient to pasteurize all of the milk, and they found that dealers would short circuit the holder if the inspector was not around. In the Long Island epidemic, blood cultures were made, but they were negative.

Case of Bullet in the Skull.—Dr. C. L. GIBSON presented this case. The *x*-ray of this skull showed apparently three bullets. The man had shot himself, he claimed, once. The policeman stated that the revolver was loaded with two cartridges and one had been fired. The *x*-ray expert insisted that the picture showed three bullets. At operation only one bullet was found, but this was split lengthwise into three symmetrical pieces.

Case of Anthrax in a Young Woman.—Dr. WILLIAM H. PARK presented this case. Ten days ago, he said, a physician of Middletown called him up about the case of a young woman who had edema of the face, following a tiny pustule like a mosquito bite. The edema spread to the chest. The chest was full of fluid and gave a pure culture of anthrax. There was no history of anthrax and no traceable source of infection. The patient died in a few days.

Dr. M. ALLEN STARR asked Dr. Park if he had an anthrax serum.

Dr. CHARLES L. DANA asked Dr. Park if he considered fur and rags the source of infection.

Dr. BREWER asked Dr. Park if it were not possible that it was communicated by flies from hides. He had had a case in a school girl which he had attributed to the bite of an insect.

Dr. C. L. Gibson said he had had two cases, both in 'longshoremen.

Dr. BREWER said he would like to ask Dr. Gibson what treatment he gave.

Dr. GIBSON said he incised and cauterized the lesions and both cases recovered.

Dr. BREWER said he made a wide incision, and used formalin dressing. The lesion was definitely localized.

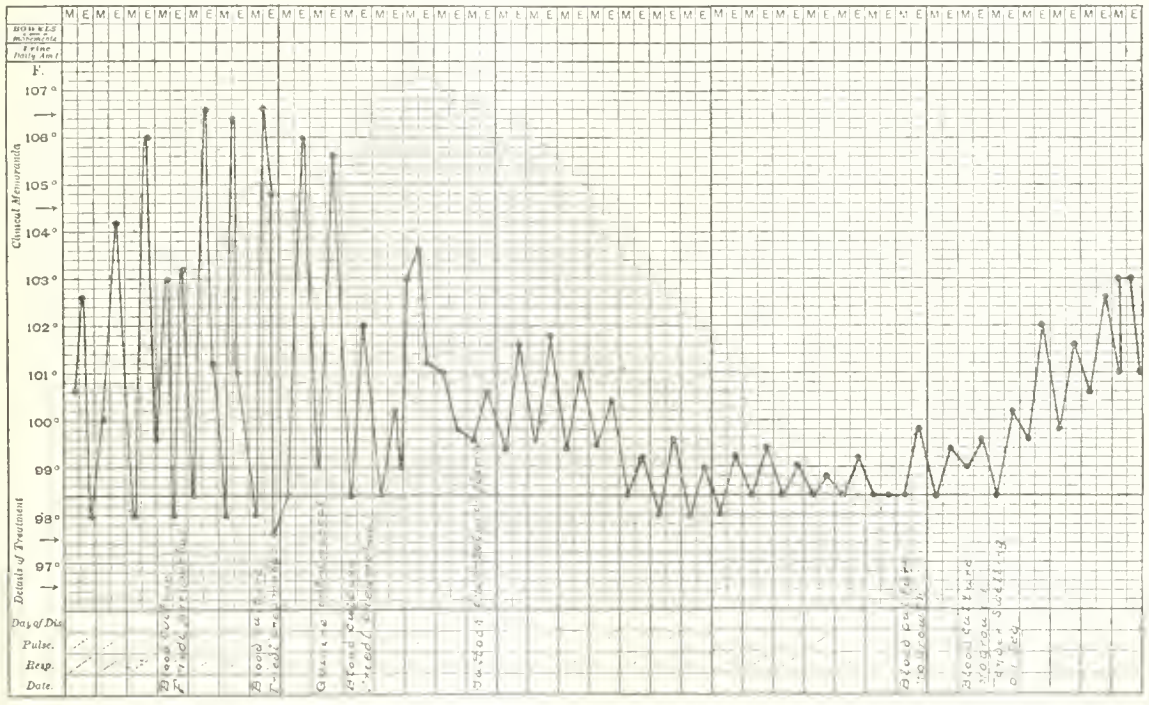
Dr. PARK said that an anthrax serum was made, but he was not sure of its efficiency. It was conceivable that flies might carry the disease.

Case of Typhoid Perforation.—Dr. A. A. SMITH presented this case. The patient was in Bellevue Hospital. He was a little more ill than the average, but not desperately so. The third week, one evening, he complained of very severe abdominal pain. He had no extra rigidity. He was nauseated, but had no particular signs except that he looked much more ill and was restless. A slight perforation was considered possible, and after long search a perforation was found; after repair a complete recovery ensued. The temperature, which was 105° before operation, fell to 101°. In cases such as these the patient should have the benefit of the doubt.

Dr. THACHER said he thought the operation rather seemed to do the patients good, even if one did not find anything. He had for some urged the advisability of operating in a case of doubt. He had had the unfortunate experience in two or three cases of suspected perforation in typhoid fever, which he had referred to the surgeons for operation, and they had refused to operate because they thought the signs of perforation inconclusive. Later they had operated and found the perforation, but the patients died.

Dr. SMITH said that in the third week the patient often had an active hemorrhage and improved afterwards. This brought out the question whether the old method of venesection had not someting in its favor. The look of increased illness of the patient often suggested perforation. In his case the abdomen was not distended and there was no increased rigidity.

Case of Sepsis from the Pneumobacillus of Friedlander.—Dr. JOHN S. THACHER reported this case, in which a cure seemed to have followed a so-called fixation abscess, or rather a sterile purulent infiltration. The patient was a tall, gaunt Greek, forty-five years of age, who said that he had been suffering for three weeks from chills and fever. These chills were severe, shaking chills, coming every second day, lasting two or three hours, followed by fever and then by profuse sweating. During the paroxysms of fever he had severe headache and felt very ill, but between the paroxysms he felt perfectly well. Entire confidence, however, could not be placed in his account, as he had a very poor command of English. After his admission to the hospital the patient's clinical picture was continued as before, except that the febrile paroxysms occurred daily, and not with entire regularity as to the hour of occurrence. The spleen was much enlarged, its edge hard and sharp. The tongue was furred and brown. The first blood count found 9000 leucocytes. A thorough physical examination of the patient, from the ear drums to the prostate, disclosed nothing further, and the case was confidently believed to be one of malarial infection. When the house staff reported that they were unable to find malarial organisms in the blood, they were jeered at and told to hunt again. After several searches for the plasmodia had been made, the patient was put upon quinine by mouth. Nevertheless for ten days after his admission the sharp paroxysms of fever continued, and on five or these days reached 106° or more. On the ninth day after his admission, an intramuscular dose of the hydrochloride of quinine and urea, 30 grains, was ordered. This was put into his left buttock. At about this time the pathlogocal laboratory reported that a culture made from his blood on the fourth day in the hospital showed an abundant growth of the pneumobacillus of Friedlander, or the *Bacillus mucosus capsulatus*. Cultures made on the seventh and ninth days showed the same growth. The diagnosis of malarial infection was therefore abandoned. The case was looked upon as one of sepsis from the pneumobacillus of Friedlander, and as this, so far as the reports of experience had gone, was an unusually fatal form of infection, the case was looked upon as practically hopeless and the treatment by quinine was stopped. On the day following his injection of quinine the temperature did not rise as high as it had been rising previously, and during the next few days the temperature was more irregular and not so high (see chart). The buttock became swollen and painful, and five days after the injection pain and other signs of inflammation were intense. After this time the temperature remained below 102° and in a few days steadily subsided, reaching normal on the tenth day after quinine had been put into the buttock. For twelve days the temperature remained normal and the patient, who insisted that he was perfectly well and was anxious to go home, was retained in the hospital only to await reports on cultures from his blood. Cultures made on the tenth and twelfth days of the non-febrile period failed to develop any bacterial growth. When the buttock was most intensely inflamed, a slight sense of fluctuation appeared and an exploring needle was in-



serted. No pus was obtained, but a serous fluid, containing blood and abundant leucocytes, but no bacteria, was demonstrated either in smears or in cultures. The inflammation in the buttock disappeared entirely without interference and without breaking down, and the patient seemed to be perfectly well. On the thirteenth day, however, after the temperature had become normal, a sore spot appeared on the lower part of the right tibia and the temperature again went up. A suppurating periostitis developed and later some erosion of the tibia and astragulus. Incisions were made by the surgeons, and the pneumobacillus of Friedlander was found in the pus. Under their care the leg recovered and the patient, seen five weeks after leaving the hospital, was evidently entirely cured and in excellent condition. This then was a case of profound general sepsis due to the pneumobacillus of Frienlander, a form of infection almost invariably fatal. In this instance prompt amelioration and ultimate cure followed an injection into the buttock which produced an intense purulent infiltration, and the interesting question arose, whether this belonged to that group of cases, reported some time ago by French observers, in which general sepsis was apparently cured by an intercurrent, sterile, so-called fixation abscess.

Dr. A. A. SMITH asked what was the explanation.

Dr. THACHER said that perhaps the great production of leucocytes produced a cure by phagocytosis.

Dr. BRANNAN asked if the spleen returned to its normal size.

Dr. THACHER said no.

Dr. PARK said that he saw by the chart that there was a sudden fall after the buttock injection. That suggested something of the kind. The fact that later he developed trouble in the periosteum suggested the process overflowed into the blood. With the present better technic, they often got positive cultures where they were not able to before.

Dr. STARR said that might account for the old-time procedure known as setons. Physicians used to make an open ulcer. They may have given benefit by increase of leucocytes. He remembered seeing patients with scars in the middle of their backs where they had had these ulcers. There wust have been some effect or they would not have been so frequent.

Dr. POLK said that was the old way of handling anal fistulas. They never touched the abscess. The patients said they felt well when the abscesses were discharging.

Dr. JAMES A. MILLER said the Health Department had sent him a tuberculous patient four years ago. She came in for examination of the lungs. She had a sloughing ulcer between the breasts. She claimed that she felt very much better with this and said that what she coughed up before now discharged from the ulcer.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

WEST VIRGINIA STATE BOARD OF HEALTH.

(*Concluded from page* 902.)

PRACTICE OF MEDICINE AND PEDIATRICS.

1. Give treatment of scarlet fever and its complications.
2. Give treatment of typhoid fever and principal complications.
3. Diphtheria, diagnosis, and treatment.
4. Give the cause, symptoms, and treatment of cerebrospinal meningitis; the symptoms of tuberculous meningitis.
5. What diseases may cause occlusion of the common bile-duct?
6. Describe the normal heart sounds and state the points on the chest where each is heard with greatest distinctness.
7. Describe briefly the following diagnostic signs or tests and name the disease or diseases in which they may be found, Koplik's spots; Romberg's symptoms; Argyll-Robertson pupil; Babinski's reflex; Kernig's sign; Stokes-Adams syndrome.
8. Give cause and treatment of "summer diarrhea" in children.
9. Describe the varieties of stomatitis, giving cause and treatment.
10. What diseases are most commonly found in the right iliac region?

SURGERY.

1. Give the morphological and clinical characteristics of sarcoma and its varieties.
2. Give the differential diagnosis between a subcoracoid dislocation and a fracture of the surgical neck of the humerus.
3. Give the symptoms and treatment of a fracture of the femur, about the middle, in a young child.
4. Give the clinical history of a typical case of osteomyelitis of the tibia in a child.
5. Give the differential diagnosis of a duodenal ulcer.
6. What must the surgeon do to prevent infection in his operative work in addition to careful aseptic precautions?
7. Give the varieties and discuss the etiology of ileus.
8. Describe in detail two methods of skin disinfection, and give the reasons for each step.
9. Give the treatment of burns.
10. What wounds are likely to become infected with the tetanus bacillus, and what prophylaxis is to be practised in the treatment of such wounds?

OBSTETRICS AND GYNECOLOGY.

1. What is the etiology of eclampsia? Discuss treatment.
2. Describe method by which the diagnosis of presentation and position can be made?
3. What is the treatment of threatened, and of inevitable, abortion?
4. Describe the changes in the mucous membrane of the uterus incident to pregnancy.
5. What are the rules governing the introduction of the blades of forceps?
6. Describe phantom tumor and give treatment.
7. What is the mesosalpinx and what does it contain?
8. What is the relation of the pubococcygeus muscles to prolapsus uteri?
9. Name the organs or parts composing the vulva and give functions of each.
10. Discuss the theories of menstruation.

SPECIAL MEDICINE

1. Conjunctivitis—give two varieties and treatment of each.
2. Glaucoma—describe and give treatment.
3. Otitis media—give causes and treatment.
4. Eustachian tube—name some of the diseases affecting it and the treatment.
5. Epistaxis—give causes and treatment.
6. Nasal catarrh (coryza)—treatment.
7. Give points at which principal heart murmurs are heard.
8. Hemorrhage from the lungs—give cause and treatment.
9. Name three curable forms of insanity and give general treatment.
10. Describe the S. Weir Mitchell rest cure.

BACTERIOLOGY AND HYGIENE.

1. Name several non-pathogenic bacteria which are useful to human life and health.
2. Name the two methods by which bacteria multiply, and state what bearing the knowledge of this has upon the methods of surgical sterilization.
3. Name five bacteria which are or may be pyogenic, and state their relative virulence.
4. Define the following: Obligate, facultative, toxin, and chemotaxis.
5. State Koch's four laws.
6. Describe a sanitary privy.
7. Give detailed directions how to rid a town of the house-fly.
8. Enumerate the important points in school hygiene, and discuss one of them in detail.
9. What is social hygiene, and what can the physician do in the course of his professional duties to promote it?
10. Discuss oral hygiene, and give the pros and cons concerning the use of the toothbrush.

ANSWERS.

PRACTICE OF MEDICINE AND PEDIATRICS.

1. *Treatment of scarlet fever and its complications.* The treatment is that of infectious fevers in general, and in addition: "1. *Serum treatment.*—Serum from convalescents, injected in doses up to 20 c.c., has sometimes proved successful. Good results have also been

obtained with polyvalent antistreptococcic sera (*i.e.* sera prepared from several different strains of cocci). 2. The danger of spreading the disease is greatest during the desquamative period. Isolation must, therefore, be kept up for at least six weeks from the onset, or till all desquamation and discharges (nasal, aural, etc.) have ceased. 3. A minimum amount of nitrogenous food, to avoid irritation of the kidneys. This caution does not affect milk, which may be freely used. 4. Daily toilet, tepid sponging, or tepid baths. 5. Inunction of oily antiseptic preparations into the skin, to prevent dissemination of the desquamating scales. 6. Examine the urine daily for signs of nephritis. 7. The condition of the ears must be carefully watched. *Complications.—Arthritis* demands warm and sedative applications. Wrap the joints in cotton wool; alkalies are better than salicylates, as the latter tend to irritate the kidneys. *Throat.*—Ice to suck; antiseptic sprays; glycerin of carbolic acid; warm applications externally. *For the severe types.*—Avoid caustic applications; relieve pain by cocaine solutions; internally, tincture of ferric chloride, with free administration of ammonia; quinine, either alone or with ferric chloride. Stimulants may also be required. Nasal feeding often gives much relief. *Nephritis.*—Milk diet, hydragogue purgatives (avoid mercurials), hot-air baths, hot packs, etc., according to the severity of the dropsy." —(Wheeler and Jack's *Handbook of Medicine.*)

2. *Treatment of typhoid fever with its principal complications:* The patient must be in bed, and no medicine given unless indicated. "Give no solid food, or that which would not readily pass through a fine sieve. Milk, if it agrees, albumin-water made from white of egg, beef tea, and chicken broth are the principal foods. Of late some authorities have advocated a light solid diet throughout, but nothing must be given that would increase the risk of perforation. The stools should be daily inspected. If undigested curd is found, milk is being given too often, or the gastric function is impaired. It may then be given with lime water or barley water. Beef tea should be sparingly used, lest it excite diarrhea. Alcohol is required mainly in the later stages, when the typhoid state has set in, and the heart is weak. Many cases do well without it altogether. Other stimulants are strychnine, ammonia, ether, etc.

"If the *diarrhea* becomes excessive give bismuth and opium, or lead acetate and morphia, or an enema of starch and opium. When the motions are very offensive intestinal antiseptics (calomel in small doses, salol, etc.), may be given. They are also useful in meteorism. If *constipation* be troublesome, give enemata. No purgatives should be given after the first week. *Hemorrhage*—opium, lead acetate, or calcium lactate gr. xv every four hours, hypodermic injection of morphine or ergotin, ice-bag to the cecum. *Perforation.*—The main chance of recovery lies in early laparotomy and suture of the affected bowel. Every hour lost after the diagnosis is made, and the initial shock has passed off, increases the danger to life. Cases operated on within twenty-four hours may recover; later, recovery is very rare. In anticipation of operation, morphine may be given to relieve pain and diminish peristalsis. *Bed sores*—water-bed, cleanliness, stimulant and antiseptic lotions, dry dressings if the slough is large. *High fever*—quinine and cold baths. The antipyrin group is dangerous to the heart. The stools and urine must be carefully disinfected. During *convalescence* the diet must be increased with the utmost caution, and the possibility of relapse must always be remembered."—(Wheeler and Jack's *Handbook of Medicine.*)

3. DIPHTHERIA. *Diagnosis* is made by finding the diphtheria bacilli in the exudate. A sterile swab is rubbed over any visible membrane on the tonsils or throat and is then immediately passed over the surface of the serum in a culture tube. The tube of culture, thus inoculated, is placed in an incubator at 37° C. for about twelve hours:, when it is ready for examination. A sterile platinum wire is inserted into the culture tube, and a number of colonies of a whitish color are removed by it and placed on a clean cover slip and smeared over its surface. The smear is allowed to dry, is passed two or three times through a flame to fix the bacteria, and is then covered for about five or six minutes with a Loeffler's methylene-blue solution. The cover slip is then rinsed in clean water, dried, and mounted. The bacilli of diphtheria appears as short thick rods with rounded ends; irregular forms are characteristic of this bacillus, and the staining will appear pronounced in some parts of the bacilli and deficient in other parts.

Treatment includes isolation, rest in bed, liquid diet, washing of the throat and nose with an antiseptic solution, and injection of the antitoxic serum. About 5,000 units may be given at once, and another dose of half this amount in from twelve to twenty-four hours if necessary.

4. CEREBROSPINAL MENINGITIS. *Cause:* the diplococcus intracellularis meningitidis. *Symptoms:* Sudden onset, pain in back of head and neck and down the spine, opisthotonos, vomiting, convulsions, cutaneous eruption, rise of temperature, and Kernig's sign. *Treatment:* Rest in bed, quiet, warmth and stimulation, withdrawal of cerebrospinal fluid by lumbar puncture and injection of Flexner's antimeningococcic serum.

Tuberculous Meningitis.—An inflammation of the soft intracranial membranes due to the deposit of gray miliary tubercles. It is usually secondary to tuberculosis elsewhere, and is seen most often in children. The onset is usually attended with various prodromes, such as irritability, anorexia, headache, insomnia, etc. The stage of excitation is characterized by headache, vomiting, convulsions, intermittent temperature, soft, irregular, and compressible pulse, and a red line upon drawing the finger-nail over the skin. This stage lasts for about two weeks and is followed by depression, in which the pulse is slow and compressible, temperature is depressed, and somnolence and stupor alternating with delirium, convulsions, headache, and peculiar shrieking are present. Collapse, coma, convulsions follow, and death usually results in from one day to two weeks."—(*Pocket Encyclopedia.*)

5. *Occlusion of the common bile duct may be caused by:* Gallstones, ulcers, foreign bodies, parasites, tumors in neighboring structures, aneurysms.

6. There are two normal heart sounds which follow in quick succession, and are succeeded by a pause. The first, or systolic, sound is dull and somewhat prolonged, the second, or diastolic, sound is sharper and shorter. The sounds may be expressed by the syllables *lubb—dup.*

The first sound is heard best at the apex beat in the fifth left intercostal space; the second sound is heard best over the second right costal cartilage.

7. *Koplik's spots* are bluish-white spots on a reddish base, found on the mucous membrane of the cheeks and lips in the pre-eruptive stage of measles.

Romberg's symptom: An ataxic patient is unable to stand steadily if his eyes are closed and his feet together; he will sway from side to side or backwards and forwards and may even fall down.

Argyll-Robertson pupil: The pupil responds to accommodation, but not to light; found in locomotor ataxia, general paralysis of the insane, cerebral syphilis.

Babinski's reflex: Irritation of the skin of the sole of the foot causes extension instead of flexion of the toes; found in lesions of the pyramidal tract, in organic (but not hysterical) hemiplegia.

Kernig's sign: The patient lies with the thighs flexed on the abdomen and the legs flexed on the thighs; if cerebrospinal meningitis is present, extension of the legs is impossible, being prevented by the contraction of the hamstrings.

Stokes-Adams syndrome: A symptom complex consisting of bradycardia, visible auricular pulsation in the veins of the neck, and vertigo or syncope; it occurs in heart-block.

8. "*Summer diarrhea in children* is a severe form of gastro-intestinal infection, due to the toxins of the bacteria in milk. It occurs in hot weather among the poor in large cities. *Treatment.* The stomach and colon should be irrigated. From 2 to 4 ounces of water at 100° F. should be allowed to flow into the stomach through a soft rubber catheter and be siphoned out. This should be done only once. For the colon, sodium bicarbonate, ʒj, should be added to the pint, and the irrigation performed twice daily. If the rectal temperature is very high, ice cold water should be used; otherwise warm water. When symptoms of collapse appear, hot pack is used. Ice water quenches the thirst, even if it is vomited. Champagne and drop doses of brandy may be given if the stomach is tolerant. Strychnine gr. 1/100-1/48, hypodermically, to a child 1 year old, is a valuable stimulant. Morphine, gr. 1/100, and atropine, gr. 1/800, may be given in the same way and repeated every hour until the child is quieted.—(*Pocket Cyclopedia of Medicine and Surgery.*)

9. "*Aphthous stomatitis* is characterized by a hypere-

mia of the mucous membrane of the mouth, and by the formation upon it of small, yellowish white vesicles of a herpetic character. Children from 6 to 18 months of age are the most commonly affected. It is due to uncleanness, improper feeding, bad hygiene, etc. The affection is self limited, but proper feeding, regulation of the bowels, and improved hygiene should be instituted, and mouth washes containing boric acid or sodium salicylate should be used.

"*Catarrhal stomatitis* is a simple catarrhal inflammation of a portion or of the entire surface of the mouth. It occurs most commonly during the period of first dentition. It results from uncleanliness, the ingestion of irritating food, infectious fevers, gastro-intestinal disturbances, etc., the mouth is red, dry, and hot; later, there is an increased flow of saliva; coated tongue, constipation, slight fever, thirst, etc., are present. The affection lasts about one week, during which sucking is painful. The treatment consist in cleansing the nipple and the child's mouth frequently, the administration of fractional doses of calomel, and the use of mild alkaline mouth washes.

"*Gangrenous stomatitis* is a rare affection, consisting of a gangrenous destruction of the tissues of the cheek, and possibly of the adjoining structures as well. It occurs in debilitated children and follows the infectious fevers. The disease progresses rapidly and terminates in death in from a few days to two or three weeks. In debilitating affections the treatment should include strict cleanliness of the mouth to prevent this condition. After it has occurred the affected areas should be excised and tonics should be administered.

"*Parasitic stomatitis* is characterized by a catarrhal condition and by the presence on the mucous membrane of white, flake like patches. It occurs usually in young infants, and is caused by a vegetable parasite (one of the mold fungi) variously known as *Oidium albicans* or *Saccharomyces albicans*. It results from uncleanliness, and the treatment is similar to that of catarrhal stomatitis.

"*Ulcerative stomatitis* is an inflammation and ulceration of the mucous membrane of the mouth, principally of the gums. It results from infantile scorbutus, infectious fevers, mercurial salivation, malnutrition, improper hygiene, etc. The symptoms include slight constitutional disturbances, reddened and swollen gums, pain and salivation, acrid, irritating and offensive saliva, foul breath, hemorrhages from the mucous membrane on pressure, etc. The treatment should first be directed toward the diet and hygiene of the patient. Salicylate of sodium, borax, or hydrogen dioxide may be used in mouth washes. Potassium chlorate should be administered internally (gr. 10-20 in 24 hours to child one year of age) and also should be used locally."—(*Pocket Cyclopedia.*)

10. *Diseases most commonly found in the right iliac region:* Inguinal hernia, psoas abscess, appendicitis, ovarian cyst or abscess, pyosalpinx, ruptured ectopic pregnancy.

SURGERY.

1. SARCOMA.—"(1) *Round-celled sarcomata* consists of a mass of round, nucleated cells with very little intercellular substance. The tumors grow rapidly, infiltrate, and disseminate. There are three varieties: (*a*) The small round-celled; (*b*) the large round-celled; (*c*) the lympho-sarcoma, in which the cells are small, but the intercellular substance consists of retiform tissue. They begin in lymphatic glands or lymphoid tissue. (2) *Spindle-celled sarcomata.*—The cells vary in size, but they are all oat-shaped, or fusiform. When much fibrous tissue is present, they are called fibro-sarcomata. Frequently patches of immature hyaline cartilage are present. (3) *Myeloid sarcomata* consist of round or spindle cells with large multinucleated cells scattered among them. The intercellular substance is gelatinous. The nuclei of the giant cells are scattered throughout, not arranged around the periphery, as in the giant cells of tubercles. They are very vascular, and may pulsate, or hemorrhage may occur in them. No secondary deposits occur, and they do not recur if completely removed. They always grow from bones, and are the least malignant. (4) *Alveolar sarcomata* are round-celled, but the cells are grouped in alveoli by distinct stroma. (5) *Melanotic sarcomata* are the most malignant. They originate from pigmented structures, the skin, and the retina. The tumor consists of round or spindle cells arranged in alveoli, the cells containing a deposit of brown pigment—melanin. The primary growth may be only slightly pigmented, and either shaped as a flat plaque or a papilloma; but the secondary deposits are of an inky-black hue. Pigmented moles are the commonest site of origin." (*Aids to Surgery.*)

2. In *subcoracoid dislocation*, the acromion process is prominent, and there is a flattening or depression below it; the head of the humerus may be felt below the coracoid process, and the glenoid cavity is empty; crepitus cannot be elicited; the head of the bone is fixed, and adduction is impossible; as a rule there is preternatural immobility. In *fracture of the surgical neck of the humerus*, the shoulder is somewhat flatter than normal; the head of the bone is in the glenoid cavity, and does not rotate with the shaft; crepitus may be obtained unless the fracture is impacted; as a rule there is preternatural mobility of the injured limb.

3. *Fracture of the middle of the shaft of the femur in a young child. Symptoms:* "As a rule, in fracture of the shaft of the femur the lower fragment is drawn upward and the upper end of the lower fragment is found posterior and somewhat to the inside of the lower end of the upper fragment, and the lower fragment also undergoes external rotation (the drawing up is due to the rectus and hamstrings; the passing inward is due to the adductor muscles; the rotation outward arises from the weight of the limb). There is complete loss of function, the thigh and leg are slightly flexed and usually everted. In some cases the leg and lower fragment are inverted. There are shortening, pain on movement, preternatural mobility, crepitus, and obvious deformity, and the ends of the fragments can be felt by the surgeon. In impaction there is alteration of the axis of the limb and some shortening. Always feel for the pulse below the fracture to learn if the artery is damaged.

Treatment: "Fractures of the thigh in children are reduced by extension and counter-extension; a well padded splint reaching from the axilla to below the sole of the foot may be applied to the outer side of the limb and body. This splint is held in place by bandages which are overlaid with plaster of Paris. It is worn for four weeks, at which time it is removed and a plaster bandage, applied so as to include the entire limb, is worn for four weeks. Bryant's extension is very satisfactory in treating a child. Both the injured limb and the sound limb should be flexed to a right angle with the pelvis, fixed by light splints, and fastened to a bar above the bed. The weight of the body produces counter-extension and the child can be easily cleaned."—(Da Costa's *Surgery.*)

5. *Osteomyelitis* is inflammation of the bone and marrow; the term is often used now for inflammation of bone.

It is *caused* by infection, the bacteria gaining entrance either through a wound, or by extension from neighboring tissues, or they may be brought by the blood.

Symptoms: Sudden onset; pain, tenderness, fever chills, swelling of soft parts; sometimes the joint can be moved gently without pain; septicemia or pyemia may be present.

It is to be *diagnosed* from (1) *Rheumatism*, in which more than one joint is affected and the tenderness is *in* the joint, and not *near* it. (2) *Tubercular arthritis*, in which the onset is slow and the trouble starts in the epiphysis rather than in the diaphysis. (3) *Cellulitis* in which the bone and periosteum are not affected, and in which there is always a wound.

In *osteomyelitis*, the *treatment* consists in relieving the constitutional symptoms and preventing the bone from necrosing. An incision down to the bone is made; if pus is beneath the periosteum, the latter is also incised; a piece of bone is removed by chisel or trephine, pus is removed, the endosteum is hurt as little as possible, the wound is irrigated with hot bichloride solution and packed with gauze; the soft parts are closed and the wound well drained. In case this fails, amputation may be necessary.

6. In *ulcer of the duodenum* the symptoms are very similar to those found in ulcer of the stomach; but in the former condition there is less tendency to vomit, the pain does not come on till some time after food has been swallowed (and has had time to pass the pylorus), and blood in the stools is more common. All of these points are due to physiological and anatomical reasons based on the relative position of the stomach and duodenum. A special sign of duodenal ulceration is the so-called "hunger pain" which occurs at the end of digestion, when the unmixed acid of the gastric

juice is passing into the duodenum. This pain is relieved by taking food, for when this occurs the pylorus closes, and the gastric juice is for the time retained in the stomach to be mixed with the food, while the alkaline duodenal and pancreatic secretions are stimulated.

7. *Intestinal obstruction* may be caused by: Strangulation, kinking, volvulus, foreign bodies, intussusception, stricture, fecal accumulation, and tumors either within or outside the bowel.

STRANGULATION	INTUSSUSCEPTION	TWISTS (VOLVULUS)
Subjective Symptoms.	*Subjective Symptoms.*	*Subjective Symptoms.*
1. Generally occurs after age of 20.	1. Most frequent in childhood.	1. Most frequent after age of 30.
2. Pain localized, rapid collapse.	2. Constant tenesmus.	2. Pain diffuse.
3. Pain intense, paroxysmal in character.	3. Pain develops suddenly and is continuous.	3. Pain paroxysmal; recurs less often than in strangulation.
4. Constipation complete.	4. Frequent diarrhea, passage of bloody mucus.	4. Constipation complete.
Objective Symptoms.	*Objective Symptoms.*	*Objective Symptoms.*
1. Temperature often subnormal.	1. Temperature normal or subnormal.	1. Temperature slightly elevated.
2. Location in small intestine.	2. Localization in small intestine; bowel frequently protrudes at rectum.	2. Location, small intestine, abdomen often protrudes, in certain areas giving dullness on percussion.

—(*Pocket Cyclopedia.*)

8. *Two methods of skin disinfection (hands and forearms):* "After mechanical cleansing a germicide is employed to render the parts sterile. Whatever method is adopted it is desirable that it shall not unduly irritate the skin." *Fürbringer's Method:* After washing off the soap in sterile water the hands are dipped in 95 per cent. alcohol and held there for two or three minutes while the forearms hands, fingers, and nails are being rubbed with alcohol. Alcohol removes the soap which has entered into follicles and creases, removes desquamated epithelium, enters under and about the nails, and favors the diffusion of the corrosive sublimate under and about the nails and into the follicles, when the hands are placed later in the mercurial solution. Alcohol also hardens epithelium and keeps it from desquamating into the wound. After using the alcohol the hands are then dipped in a hot solution of corrosive sublimate (1:1000), and with the forearms are scrubbed for at least a minute, the nails receiving especial care.

The Sublimate Alcohol Method: It is as follows: Cleanse the hands with soap and water as previously directed. Use 95 per cent. alcohol as in Fürbringer's method. Dip the hands in 70 per cent. alcohol containing 1 part to 1000 of corrosive sublimate, and rub the hands, forearms, and nails with a piece of sterile gauze wet with this fluid for three minutes. Rinse these parts in the fluid and then rinse in sterile water." —(Da Costa's *Surgery.*)

9. *Treatment of Burns.*—General: If carbonic-oxide-poisoning is present, artificial respiration and administration of oxygen. For shock, opium and stimulants. Local: For burns of the first degree, powder with boracic acid. Puncture blisters, and cover the part with an antiseptic dressing. Burns of deeper degrees than the second must be made aseptic with 1 in 1,000 perchloride of mercury. Carbolic acid is absorbed readily, and must not be used. Antiseptic gauze dressings should then be used. Picric acid (20 grains to 1 ounce of water) is used as a dressing. It lessens the pain, and can be left on two or three days. The continuous bath may be used. If the burn be of any size, it should be skin-grafted, as the scars of burns contract very much, and may produce deformities.—(*Aids to Surgery.*)

10. Punctured wounds, and those made with an implement which is dirty or which is infected with the tetanus bacillus are the most likely to result in tetanus. Such wounds should be disinfected before being dressed; and all wounds which have been exposed to infection by earth, dust or stable refuse should be thoroughly purified. The use of Antitetanic Serum has been recommended by some surgeons.

OBSTETRICS AND GYNECOLOGY.

1. PUERPERAL ECLAMPSIA. *Etiology:* Urema, albuminuria, imperfect elimination of carbon dioxide by the lungs, medicinal poisons, septic infection; predisposing causes are renal disease and imperfect elimination by the skin, bowels, and kidneys.

"*The prophylactic treatment* consists in frequent and regular examination of the urine. After the first appearance of albumin, daily quantitative examination of the urine should be made. The diet should be milk; the bowels should be kept freely open by means of calomel and salines; the skin should be kept active by hot baths, followed by vigorous rubbing. Diuretics, such as Basham's mixture, digitalis, and caffein, should be administered. During pregnancy, if the percentage of albumin increases in spite of the treatment, abortion or induction of labor is indicated.

"*The treatment of the attack* consists of the administration of chloroform by inhalation, chloral hydrate (gr. 60) by enema, and the fluidextract of veratrum viride hypodermically (gtt. 15 followed by gtt. 5, repeated frequently enough to keep the pulse at about 60 beats a minute), to control the convulsions, and free purgation by croton oil (gtt. 2, or 3, in sweet oil or glycerine), free sweating by the hot pack, and sometimes depletion by venesection to eliminate the poison. The after-treatment consists of free purgation by the salines, restriction of diet, and later the administration of tonics and stimulants. The obstetric treatment is usually noninterference." (*Pocket Cyclopedia.*) Sometimes *accouchment forcé* is indicated.

2. *Methods of determining the position of the fetus prior to labor:*—"The examiner stands alongside the patient, facing her head; the tips of the fingers of both hands, moving together and at equal distances from the middle line, are carried up the sides of the abdomen by a series of tapping movements; and upon one side (for example, the left, in the L. O. A. position) is noticed a firm, broad, even sense of resistance, contrasting with the cystic, tumor-like sensation of the other side, with the occasional encounter of firm, irregular bodies,—the fetal extremities. This firm, broad, even resistance is produced by the fetal back, and, to confirm this fact, the extremities are felt for by a rubbing motion with one outstretched hand on the opposite side. They are felt as cylindrical, irregular bodies, slipping away from the hand, and changing their position from time to time. Having located the back and the extremities, the portion of the fetal ellipse presenting at the superior strait is next ascertained. The examiner now faces the woman's feet, and, with the outstretched hands, the fingers parallel with and the middle finger over the center of Poupart's ligament, on either side, the fingers dip down beneath the ligament into the pelvic cavity. If the head is presenting, it is felt as a hard, regular, round body, the greater mass of the occiput, the sharp point of the chin, and the groove between occiput and back being often distinguishable. At the same time, the density of the head, its compressibility, its approximate size, and its relative size to the pelvis may be learned. By *auscultation* the fetal heart-sounds are located, and their rate and intensity are noted. The uterine bruit and the funic souffle are often heard. The former is a low-pitched musical murmur synchronous with the maternal heart-beat. The latter is a high-pitched whistling murmur synchronous with the fetal heart-beat. The position of the abdomen at which the fetal heart-sounds are heard with greatest intensity is of diagnostic value in confirming the find, by abdominal palpation, as to position and presentation. By *vaginal examination* the finger detects the varying portions of the fetal body which may present at the superior strait, as the cranium, the face, the shoulder, the buttocks, the knees, feet, and, exceptionally, the elbow or hand."—(Hirst's *Obstetrics.*)

3. "*Treatment of threatened abortion* includes rest in bed with absolute quiet; the administration of nerve sedatives, preferably suppositories of opium, one grain of the aqueous extract morning and evening; this may be supplemented by teaspoonful doses of the fluid extract of viburnum prunifolium four times daily. If the abortion is due to general disease, such as typhoid fever, pneumonia, phthisis, or valvular heart disease, no attempt should be made to prevent it."

Treatment of inevitable abortion: "If the preceding plan of treatment fails and abortion seems inevitable, the emptying of the uterus should be hastened.

Two methods of treatment have been advised for these cases. The first is the *expectant plan*, which may be described briefly as follows: Place the patient in bed, and if the bleeding is profuse, insert a tampon of iodoform gauze (1 yard) well up against the cervix. If this fails to control the hemorrhage, reinforce it by

another yard or two of gauze and a perineal pad and binder. Small doses (5½) of the fluid extract of ergot should now be given every 2 or 3 hours. At the end of from 8 to 12 hours remove the tampon, when the ovum may be found extruded from the cervix; if not, a vaginal douche of mercuric chlorid; (1:4000) must be given, and another tampon introduced. If, upon the removal of this second tampon at the end of 10 or 12 hours, the ovum is not discharged, then more vigorous methods to secure its expulsion must be adopted.

The active plan comprises the following: The physician's hands and instruments are sterilized; the patient is etherized and placed on an appropriate table, or across the edge of the bed, her buttocks resting upon a Kelly pad; the genitalia are thoroughly cleansed and a vaginal douche of mercuric chloride (1:4000) is given; the anterior lip of the cervix is brought down to the vulvar orifice; the cervix is dilated if necessary; the placental forceps are introduced into the uterus, and as much as possible of the ovum is removed; the uterus is thoroughly cureted, and an intrauterine douche of sterile water is given. A light tampon of iodoform gauze is placed in the vagina; the patient is then returned to bed.

A strip of gauze may be placed in the uterus in cases of sharp retroflexion, to secure free drainage, and occasionally an intrauterine tampon will be necessary when the uterus refuses to contract and hemorrhage persists after the use of the curette."—(*Pocket Cyclopedia.*)

4. "As a result of impregnation the mucous membrane of the uterus undergoes certain changes in structure, and is henceforth known as the decidua. The fertilized ovum may enter the uterus at any stage of the menstrual cycle. The surface of the endometrium may not be quite smooth, and the ovum may possibly be arrested by some ridge or projection of the surface. Here it embeds itself, and the destructive and invasive action of the syncytium is soon followed by a reaction on the part of the uterus. This reaction is characterized by a rapid transformation of the small, primitive, connective tissue cells of the stroma of the endometrium into large oval or polygonal 'epithelioid' cells with large pale oval nuclei. These are the decidual cells, and they are probably thrown out as a line of defence against the advance of the syncytium (Turner). The glands of the endometrium become enlarged and dilated, the capillaries distended with blood, and the whole membrane becomes markedly thickened and soft and edematous. Instead of being only about one-eighth of an inch thick, it swells until it may even be as much as half an inch in depth. In this growth the glands take a very active share, and increase so much in length that in order to accommodate themselves, they become folded backwards and forwards in their middle parts. The effect of this is to make the middle portion of the decidua full of distended gland spaces, whereas the more superficial portion contains only the mouths and necks of the glands supported in a stroma packed with the decidual cells. If a section be made through the decidua, it thus appears to be divided into three layers, the superficial part being compact in structure, and hence known as the superficial compact layer, while the deeper part is known as the spongy layer. The deepest part of all, immediately next the muscle wall, contains only the blind ends of the glands (many of which actually penetrate the muscle), and is sometimes described as a third layer, the deep compact layer. For purposes of description the decidua is divided further into three parts according to its relationship to the ovum. The part on which the embedded ovum rests is called the decidua serotina; the part superficial to it is called the decidua reflexa, and the decidua lining the rest of the cavity of the uterus is called the decidua vera."—(Johnstone's *Midwifery*).

5. *Manner of using forceps:* "They should not be used when the os is undilated, when the head is not engaged, except in placenta prævia, when the membranes are unruptured, when the disproportion between the child's head and the parturient canal is too great, or in impossible positions and presentations. Before applying the instruments they should be sterilized, preferably by boiling; and the patient anesthetized and placed in the lithotomy position. Two fingers of the right hand are introduced into the vagina; the left blade of the forceps is then held almost perpendicularly by the left hand, with the tip of the blade opposite the vulva; the tip is introduced into the vagina, passed along the floor toward the sacrum. The blade is rotated outward in its long axis in order to escape the promontory of the sacrum. The right blade is introduced in a similar manner. To facilitate locking, one of the blades must be rotated forward. If the head occupies the right oblique diameter, as in L. O. A. and R. O. P. positions, the right blade must be rotated; if it occupies the left oblique diameter, the left blade must be rotated. Traction is made in the direction of the pelvic axis until the perineum is well distended. The perineum is then protected by one hand, while the face is swept over it by an upward movement of the forceps. In posterior positions it is necessary to remove the instruments after the head is drawn down to the pelvic floor; after anterior rotation is secured they may be reapplied. If the occiput rotates into the hollow of the sacrum the hands should be depressed as the face is swept out under the symphysis pubis."—(*Pocket Cyclopedia.*)

6. Phantom tumor may be a "pseudocyesis," a condition in which the patient (erroneously, but honestly) believes herself to be pregnant. She may present some of the subjective signs of pregnancy, with increase in the size of the adbomen; but the cervix is unaltered, the uterus is not enlarged, and there are no fetal movements. The diagnosis is made by giving an anesthetic when the abdominal swelling diminishes in size. The difficulty lies in getting the patient to believe that she is not pregnant; perhaps the best method is for a friend of the patient to be present during the examination under anesthesia and to witness the diminution of the swelling. No treatment is indicated.

7. The *mesosalpinx* is that part of the broad ligament beneath the Fallopian tube; it consists of two layers of peritoneum with a little connective tissue, and contains the organ of Rosenmueller.

8. It was formerly believed that a ruptured perineum was the main, if not the only factor in causing a prolapse of the uterus. This is no longer accepted as true. Of course if the perineum is completely torn prolapse is more likely to occur, but the perineum is only one factor in the case. The levator ani is one of the perineal muscles, and the pubo-coccygeus is one of the divisions of the levator ani. In an ordinary perineal laceration in the median line, even if it extends into the rectum, very few fibers of the pubo-coccygeus are torn. Hence this muscle cannot be considered as having much of a causal relationship to prolapse of the uterus.

9. The *vulva* consists of the labia majora, labia minora, clitoris, hymen, vestibule, fossa navicularis, and mons Veneris. All these parts are endowed with great sensibility, and are mainly concerned with the function of coitus; in addition, the clitoris is regarded as being the main seat of sexual sensation and pleasure; the mons Veneris is said to prevent irritating secretions from the skin trickling into the vulval cleft; the hymen is a membrane closing (partially) the entrance into the vagina.

10. *Menstruation* is a periodic discharge of blood from the mucous membrane of the uterus, due to a fatty degeneration of the small blood-vessels. Under the pressure of an increased amount of blood in the reproductive organs, attending the process of ovulation, the blood-vessels rupture, and a hemorrhage takes place into the uterine cavity; thence it passes into the vagina. Menstruation lasts from five to six days, and the average amount of blood is about five ounces. It begins at puberty and occurs periodically at about 28 days interval, until the menopause; it is absent during pregnancy and early lactation.

The relation existing between ovulation and menstruation is not known. The two processes are usually coexistent, but they may be independent of each other. The following theories have been held: (1) Menstruation is dependent upon ovulation; (2) ovulation is dependent upon menstruation; (3) they are independent of each other; (4) they both depend upon some other (at present unknown) cause.

Menstruation has been considered as being analogous to the condition of "heat" or "rut" in the lower animals.

SPECIAL MEDICINE.

1. ACUTE CONJUNCTIVITIS. *Etiology:* Irritation, a foreign body, cold, exposure to strong light or heat, eyestrain, disordered secretion of tears. *Symptoms:* Hyperemia, lacrimation, epiphora, discharge, photophobia, sensation of sand in the eye, symptoms are worse in evening. *Treatment:* Remove cause if possible; use astringent and antiseptic washes; anoint the lids with vaseline; alum, tannic acid, zinc sulphate, or silver nitrate have all been recommended. When it becomes contagious, its common name is "pink-eye."

OPHTHALMIA NEONATORUM. *Causes:* The gonococcus or some other pyogenic microorganism; the secretions of the mother contain the infecting agent, and transmission may occur directly during parturition, or indirectly by the fingers of physician or nurse, cloths, instruments, etc. *Symptoms:* Swollen eyelids, with copious purulent discharge; ulceration of the cornea may ensue. *Prophylaxis:* Whenever there is the possibility of infection, or in every case, wash the eyelids of the newborn child with clean warm water, and drop on the cornea of each eye one drop of a 1 per cent. solution of nitrate of silver, immediately after birth. *Treatment:* Wash the eyes carefully every half hour with a saturated solution of boric acid; pus must not be allowed to accumulate. Two drops of a 2 per cent. solution of nitrate of silver must also be dropped on to the cornea every night and morning. The eyes must be covered with a light, cold, wet compress. The patient must be isolated, and all cloths and compresses used must be burnt.

2. *Glaucoma* is a diseased condition of the eye, produced by increased intraocular pressure, and resulting in excavation and atrophy of the optic disc, and blindness. It is due to increase of the contents of the eye, hypersecretion, retention, old age, gout, rheumatism, nephritis. *Symptoms:* Visual disturbances, increased ocular tension, hazy and anesthetic cornea, sluggish and dilated pupil, shallow anterior chamber, ciliary, neuralgia, cupping of optic disc, blindness. *Treatment:* Myotics, such as eserine or pilocarpine; massage of the eyeball; mydriatics are contraindicated; operative treatment may include paracentesis, iridectomy, or sclerotomy.

3. *Acute catarrhal otitis media* is frequently caused by acute coryza and the infectious fevers. There is a painless obstructed sensation in one or both ears, impairment of hearing, and tinnitus. The inflammation causes closure of the Eustachian tube. Inflation and aspiration of the middle ear and syringing and douching the nares and nasopharynx must be avoided. A moderate spray of Dobell's solution may be used. If pain is present, dry heat, in the form of hot-water bottle, hot stone wrapped in flannel, etc., may be applied. A few drops (100), warmed, of a carbolic acid solution (1:40), or one of formalin (1:2000), may be instilled into the ear.

"*Acute purulent otitis media:* Acute catarrhal otitis media, instead of undergoing resolution, may pass into acute purulent otitis media (especially in exanthemata) from the passage of pathogenic germs from the nasopharynx into the middle ear. The pain will become more intense, the hearing dull; tinnitus will become louder and more distressing, and fever usually sets in. Dry heat allays the pain. Warmed water or warmed carbolic acid solution (1:40) may be used. Inflations, aspirations, etc., should be avoided. If the nares are filled with tough secretions, a spray of Dobell's solution may be used. If the pain continues over six hours in a child or over twelve hours in an adult without spontaneous perforation of the tympanic membrane, paracentesis of that structure should be performed. The concha and meatus should be smeared with petrolatum to avoid chapping, and the secretions should be gently mopped off as they appear. Under this treatment the ear usually returns to normal in two to three weeks." —(*Pocket Cyclopedia of Medicine and Surgery.*)

4. *Eustachian tube, diseases of:* Catarrh (acute and chronic) and obstruction. Cleanse the postnasal space, and inflate the Politzer bag or bougie. Dover's powder may be given at the commencement of an acute catarrhal condition.

5. EPISTAXIS. *Causes:* Ulceration, foreign bodies, anemia, cardiac hypertrophy, fracture of nose, purpura, hemorrhagic diathesis, nephritis, typhoid. *Treatment:* (1) Try to cauterize the bleeding point; (2) plug the nasal cavity with gauze soaked in adrenalin; (3) inject into the nares a solution of peroxide of hydrogen; (4) plugging the nares, anteriorly and posteriorly; (5) an inflating plug may be used.

6. The treatment of nasal catarrh consists in rest in bed, the administration of fractional doses of calomel followed by a saline, hot foot baths, hot drinks, quinine, Dover's powder, and a combination of belladonna, opium, and camphor water. The local treatment consists in a gentle spray with an alkaline solution, and the application of a mixture of one ounce of liquid vaseline and four grains of menthol.

7. The *mitral regurgitant murmur* is heard best in the center of the mitral area, above and to the left of the apex.

The *aortic obstructive murmur* is heard best in the midsternum or to the right of it; opposite the third rib or second interspace.

The *aortic regurgitant murmur* is heard best in the midsternum opposite the upper border of cartilage of third rib.

The *mitral obstructive murmur* is heard best over the mitral area around the apex.

The *tricuspid regurgitant murmur* is heard best in the midsternum just above the ensiform cartilage.

The *tricuspid obstructive murmur* is heard best in the midsternum opposite the cartilage of the fourth rib.

The *pulmonary obstructive murmur* is heard best in the second interspace to the left of the sternum or at the level of the third rib.

The *pulmonary regurgitant murmur* is heard best in the second left interspace.

8. *Hemorrhage from the lungs* may be *caused* by:—Injury, severe coughing, purpura; it occurs in phthisis, pneumonia, abscess or gangrene or cancer of the lung, affections of the mitral valve, aneurysm. *Treatment:* "Unless a large artery is opened, bleeding usually ceases spontaneously, and the patient should be reassured. Absolute rest and quiet, light food given cold, ice to suck and injections of morphine and atropine suffice in the majority of cases. Inhalation of nitrite of amyl is a valuable measure. Ergot raises the intrapulmonary blood pressure and may do harm. In protracted cases, saline purgatives and aromatic sulphuric acid are indicated. Adrenalin is useless." —(Wheeler and Jack's *Practice of Medicine.*)

9. *Three curable forms of insanity:* Some forms of mania, melancholia, and delusional insanity.

In a general way, rest and change of environment are necessary; removal of constipation and dyspepsia is essential; sleep is beneficial, frequent bathing with friction of the skin is useful. In mania, a hot or warm bath reduces the excitement; hyoscine or chloral may quiet the patient and produce sleep; the food must be nutritious and easily digested; and the patient must be removed from his friends. A kind, but firm and judicious nurse is invaluable.

10. "The '*Weir Mitchell*' *treatment* is a systematized plan by which the weakened body is placed in thorough condition, by means of continuous rest, enforced feeding, and regular muscular waste produced by massage, which enables food to be taken and assimilated. The essentials of this method are:

(1) Complete rest, the patient being placed in bed, and kept there during treatment; and it should be a *sine qua non* that this rest should not be in the patient's own house, but in a medical home or in lodgings, the friends and relatives, whose influence is often most injurious, being strictly excluded.

(2) Regular muscular exercise to produce tissue waste, by means of massage of the whole body, at first for ten minutes or a quarter of an hour, twice daily, soon increased to an hour or an hour and a half. The influence of this is often misunderstood, and this treatment is frequently erroneously talked of as a 'massage treatment.' It should be borne in mind that massage is nothing more than a remedial agent, used for a specific purpose; that it is not the most important part of the cure; and that, used alone, and without enforced rest and over feeding, as is unfortunately so often done, it cannot possibly be productive of any real good.

(3) Feeding is the most essential part of the treatment. At first the patient should be placed on milk alone, about five ounces every third hour. Within a few days this is increased to ten ounces, so that at least two quarts are taken in twenty-four hours. Then, by degrees, solid food is added, so that within a fortnight the patient should be taking three large mixed solid meals daily, in addition to the milk, and often a cup of strong soup, with two teaspoonfuls of beef peptonoids added, twice daily as well. This exaggerated diet is continued for six weeks or two months, when it is gradually lessened, the massage also being discontinued, and the patient allowed to get up. In an average case the patient should gain from fourteen to twenty-three pounds during this time. It is strange to see how, with returning health, all invalid habits are lost, sleep becomes regular without drugs, the bowels cease to require assistance, and the whole appearance, and apparently even the nature, of the patient is altered.

At the end of the treatment, in most cases, it is advisable that the patient should go for a change, either on a sea voyage or abroad, so as to complete the cure.

At any rate, she should not return to her family until her health is re-established. The essential point to remember is that no half measures should be permitted: if this treatment is not carried out thoroughly and completely, it had much better not be tried at all."—(Quain's *Dictionary of Treatment.*)

BACTERIOLOGY AND HYGIENE.

1. *Clostridium pasteurianum; Nitroso-bacteria; Nitrobacteria;* various bacteria of the genera. *Thiothrix, Chromatium, Spirillum, Monas, Crenothrix, Cladothrix, Leptothrix; Bacterium aceti; B. pasteurianum; Bacillus chauvæi; Saccharomyces cerevisiæ.*

2. Bacteria multiply by fission (or division), and also by spore-formation. Spores are much more resistant to heat than the bacteria without spores. Hence the process of fractional sterilization is adopted by the surgeon. Sterilization on the first day kills all the non-spore forms, while the spores remain alive. The next heating kills such spores as have assumed the non-spore form. The third heating probably kills the remainder.

3. *Five pyogenic bacteria.—Streptococcus pyogenes, Staphylococcus pyogenes aureus, Staphylococcus pyogenes citreus, Staphylococcus pyogenes albus, Micrococcus tetragenus.*

4. An *obligate aerobe* is a bacterium that can only exist in the presence of oxygen; an *obligate anaerobe* is one that can only exist in the absence of oxygen.

A *facultative acrobe* or *anaerobe* is one that can exist either with or without oxygen.

A *toxin* is the poisonous product of bacteria.

Chemotaxis is the property by virtue of which certain living cells approach (*positive chemotaxis*) or move away from (*negative chemotaxis*) certain other cells or substances.

5. KOCH'S FOUR LAWS. To *prove that bacteria causes disease* it is essential: (1) That the microorganism be found in the tissues, blood, or secretions of a person or animal sick or dead of the disease; (2) the microorganism must be isolated and cultivated from these same sources; it must also be grown for several generations in artificial culture media; (3) the pure cultures, when thus obtained, must, on inoculation into a healthy and susceptible animal, produce the diseases in question, and (4) the same microorganisms must again be found in the tissues, blood, or secretions of the inoculated animal.

6. *A sanitary rural privy* consists of a "small watertight pit, not drained but roofed over to exclude rain, and so arranged that the excreta and ashes become thoroughly mixed. For this purpose either the ashes must be thrown in through the closet seat, which may be hinged so as to be lifted *en masse*, or else a "shoot" or sloping slab must conduct one and the other to a common point. The floor should be smooth, and raised a few inches above the level of the adjoining ground.

"The contents ought to be removed at fixed short intervals, and the work should be done at night or early in the morning so as to minimize the nuisance."—(Whitlegge and Newman.)

7. "Since flies breed only in filth, the first thing to do is to render it impossible for the fly to reach any of the accumulations unavoidable around habitations. This is done: (1) By destroying filth wherever found. (2) By rendering it distasteful or poisonous to flies or their larvæ by the use of lime, kerosene, oil of pennyroyal or cresol. (3) By excluding light from the receptacle or by screens which the flies cannot pass. The most difficult part of an anti-fly campaign is teaching the people to dispose of their garbage properly. No amount of screening, trapping or poisoning, will make up for careless disposal of filth and waste. All such materials must be promptly destroyed or buried. If a really good suspension of milk of lime (calcium hydrate) is mixed with the garbage or refuse, the eggs and pupæ or maggots of the fly are at once destroyed, but it must be made to come in contact with the eggs or maggots to do any good. Kerosene oil is more effective, but more expensive. Where crude oil or low grade distillates are procurable, the expense is much lessened. Oil of pennyroyal, in the proportion of 1 ounce to 1 quart of kerosene, is very distasteful to the adult fly, as well as fatal to the young, and a small quantity sprinkled around the garbage can is sufficient to keep away all flies. The greatest drawback is the expense. Cresol is not expensive, and may be used freely in 2 per cent. emulsion. Privy vaults, manure bins, and similar places must be made and kept perfectly dark. Screens must be made automatically self-closing, otherwise they are sure to be left open and to fail of their object."—(Gardner and Simond's *Practical Sanitation*). Fly poisons, flytraps and fly papers may also be used.

8. *Concerning schools:* The school building should be as near as possible to the center of the area which it is to serve; the site should be airy and open, of sufficient size, free from swamps, and somewhat elevated; it should not be too near factories, busy streets, or railways; the soil should be as free as possible from organic matter. The buildings should be so planned that the corners look towards the four points of the compass. In this way the sun will have access to each side and to every room during some part of the day. The building should have as few stories as possible. The walls should be of brick or stone, and should be pointed with cement; the inner surface of the wall should be cemented smooth. The foundations must be solid. The general arrangement will depend upon size of site, number of scholars, and number of required rooms. Fifteen square feet per child should be allowed. Details will have to be considered on: plans, accommodations to be provided, shape and size of class rooms, distribution of rooms, teachers' rooms, corridors, entrances and staircases, playground, ventilation, heating, lighting, and placing of windows, sanitation, lavatories, water supply, drinking water, sewage disposal, removal of refuse, sanitary appliances, and drainage. Special care must be given to the prevention of contagious diseases and the exclusion of all possible sources of infection or contagion; there should be physical examination of children, also, for noncontagious physical defects.

The principal means of preventing the spread of contagious diseases in schools are: Regular and efficient inspection by physicians; prompt exclusion and isolation of any one suffering from a contagious disease, or coming from a house where such disease is; compulsory notification of all infectious and contagious diseases; individual towels, drinking vessels, and other implements; children who have had a contagious or infectious disease or who have come from a house where such disease prevailed should not be readmitted to school until sufficient time has elapsed since the occurrence of the last case to insure safety.

9. *Social hygiene* is a term with no exact meaning, but which is often euphemistically applied to venereal prophylaxis—the prevention and control of venereal diseases. The physician can advise parents about the proper supervision of their children's leisure, amusements, companionships, and tendencies; he should urge physical exercise upon such as need it, but are disinclined to take it. He can recommend the adaptation of schooling and vocational training to the child's nervous system. He can suggest to the parents instruction in the basic facts of sex as the child attains to puberty, and in the venereal perils thereafter. Upon request, he should himself undertake this instruction. He should employ every legitimate means to insure that venereal patients under his care do not marry until they are cured, impressing upon them the seriousness of the consequences if they disregard this advice.

10. The mouth and teeth should receive especial attention in the way of cleanliness. The hygiene of the mouth is of the first importance and may be a means of preventing disease. The teeth should be cleansed with a brush of suitable size, having bristles neither too hard nor too soft, and a handle bent at such an angle with the bristles that the latter may be able to reach all the surfaces of the teeth; the bristles should be of unequal length, and the brush must be kept clean. An improper brush, with bristles either too hard or dirty, may do harm, and has been held responsible for pyorrhœa alveolaris; but a suitable tooth-brush can effect nothing but good. The mouth and teeth should be cleaned morning and night, and if possible, after meals. In this way particles of food may be removed, fermentation checked, decay prevented, bad breath prevented or lessened, and dyspepsia warded off.

Post-Anesthetic Glycosuria.—Ross and McGuigan in some experimental work with dogs came to the conclusion that ether anesthesia causes a rise in the sugar content of the blood—hyperglycemia; that this hyperglycemia was greater, if the dogs had been fed meat only; and that the anesthetic itself, and not the asphyxia or excitement, is responsible for the increased quantity of sugar in the blood.—*Journal of Biological Chemistry.*

A CASE OF SPONTANEOUS PYOPNEUMOTHORAX COMPLICATED BY HYDRO- OR PYOPNEUMOPERICARDIUM.*

BY ALFRED MEYER, M.D.,

NEW YORK.

CASES of pneumopericardium and its allied diseases of hydropneumopericardium and pyopneumopericardium are so rare that the vast majority of medical men have never seen one.

FIG. 1.—Pneumothorax; tuberculosis right lung. Dorsoventral skiagram, with patient upright. Shows pericardium separated from heart ½ in. P, pericardium; L, compressed lung; Pn, Pneumothorax.

In 1904 W. B. James published a case of his own and could collect from the literature a series of only thirty-eight other cases. In his very excellent article he quotes Schroetter as saying, "The infrequency of the presence of air or gas in the pericardial space may be gathered from the fact that I never had an opportunity of observing such a case in thirty-five years' diligent study of the enormous clinical material offered by the City Hospital (Vienna), while our predecessor and teacher, Skoda, had the same experience."

I, however, have been able to add ten more cases† to James' list, published before his article appeared, which were no doubt accidentally omitted, and the four following cases were published since the appearance of his article; that of John Cowan in 1912; Wenckebach, in *Zeitschr. f. klin. Med.*, Berlin, 1910, LXXI-402; Ljungdahl, in *Deutsches Arch. f. klin. Med.*, Leipz. 1913, CXI, 19-28, and J. Burke, *Buff. Med. Jr.*, 1908, LXIV, 531.

The interest of Cowan's case and that of Wenkebach, which was one of artificial pneumopericardium and was illustrated, is much enhanced because of the fluoroscopic and skiagraphic findings, of which latter characteristic plates are reproduced. So far as I could find, they are the only radiographs of pneumopericardium extant besides my own.

The object of the present paper is to publish the records of a case in which a hydro- (pyo-?) pneumopericardium was present together with a pyopneumothorax, a combination apparently so rare that a diligent search of the literature made for me at the library of the New York Academy of Medicine has failed to find a similar one. It is true, Baeumler says, with reference to prognosis in pneumopericardium, that the rupture of a pneumothorax or even a pulmonary cavity into the pericardium can heal spontaneously, but he gives no cases or references, or other indication that he has seen such a combination. The nearest approach to the case observed by me is the one published by Lundie; this was a case of spontaneous left pneumothorax in a young man of 20 years with recovery in about three weeks *and then followed* by a hydropneumopericardium from which he also recovered; in other words

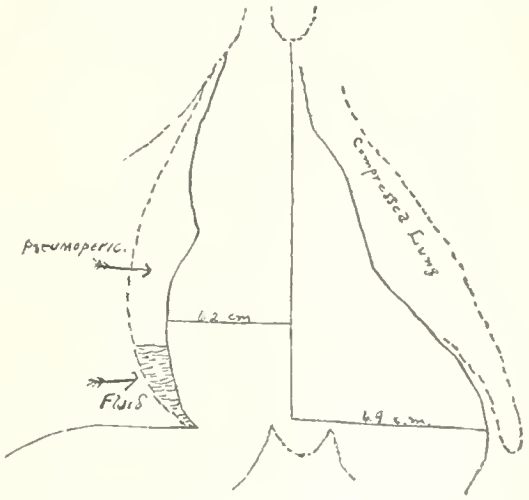

FIG. 2.—Orthodiagram of the chest.

the two conditions were not present at the same time.

My own case is that of a male, B. B., peddler, 29 years old, who was admitted to my service at Mt. Sinai Hospital on December 12, 1914. He claimed to have had a cough for a period of six months, with dull pain in

*Read before the Medical Section of the Academy of Medicine, Oct. 19, 1915.

left chest, becoming acute, sharp and constant *two days before admission;* expectoration for three months and night sweats for only a few days; his weight having dropped to 120 pounds from 175 pounds in six months.

My first examination was made two days after his

FIG. 3.—Oblique skiagram showing pneumopericardium with fluid at base of pericardial cavity. P, pericardium; Pf, fluid in pericardium.

admission. His rectal temperature was ranging between 100° and 104°, pulse from 96 to 132, and respiration from 28 to 36; tubercle bacilli had already been found in his sputum several times. There was dullness at the right apex to the third rib with much crepitation; on the left half of the chest, both anteriorly and posteriorly, the ordinary signs of pneumothorax were present, (tympany, absent respiratory murmur and voice, and decreased mobility) *but no succussion.* The heart's borders could not be mapped out and its sounds were best heard to the right of the sternum; but the most interesting and unexpected physical finding was a *peculiar amphoric or metallic tinkling or splash,* sometimes with systole and sometimes with diastole.

In a rather extensive experience with both spontaneous and artificial pneumothorax, I had never heard a similar physical sign, and I strongly suspected the existence of both fluid and air in the pericardial sac to account for this remarkable phenomenon. It must be noted that at this time there was not yet proof of pus in the pleural cavity, nor was any succussion sound to be elicited by the usual maneuver.

A skiagraph of the chest taken on December 15 showed a nearly complete pneumothorax of the left side, the left lung collapsed and its edge forming a perpendicular line in the parasternal line. *A linear shadow was seen along the right border of the heart and parallel with it. Its exact significance was undetermined.*

On December 17, the peculiar splash above described was audible in the precordial region and just below the angle of the left scapula. On this date a fluoroscopic report of the chest says: "A linear shadow to the right of the heart runs parallel with its right border. A study of the relation of this shadow to the heart indicates that it probably represents the pericardium. There is evidently here a pneumopericardium which occupies the right and anterior portion of the pericardial cavity, displacing the heart backward. There also appears to be a small effusion at the base of the pericardium on the right side."

Orthodiagram on December 19 showed the following: "The heart is displaced somewhat to the right together with the mediastinum. On the right side the pericardial cavity is seen to contain air. At its base is seen a fluid level agitated by each beat. A lateral examination shows the pericardial cavity anterior to the heart full of air crowding the heart back. The collapsed left lung is seen lying close to the left border of the heart, a small layer of gas, possibly in the pericardium, intervening." (See Fig. 2.)

Physical signs of effusion in the left pleural cavity appeared on December 21, with dullness in the sixth left interspace when seated; one inch below this when lying down. Succussion was also elicited. The heart borders could not be mapped out very distinctly and the heart sounds had a musical character. Tympany extended to the right of the midsternal line a distance of

1 cm. at the level of the 2nd rib
3 cm. at the level of the 3rd rib
6.5 cm. at the level of the 4th rib
8 cm. at the level of the 5th rib

Fluoroscopic report on December 23 showed "a left pneumothorax with unquestionable evidence of fluid in the left chest, the latter showing tumultous waves due in all probability both to respiratory and cardiac influence. The right border of the pericardium seems to be more to the right than at the first examination. An interval between the heart and the pericardium seems to be greater, as if the pneumopericardium had either increased or had become more apparent. A small amount of fluid in the pericardial cavity reaches about one inch above the inferior surface. *The fluid in the pericardium can be seen undulating apparently with the cardiac impulse." The report should also have stated that the level of the fluid in the pericardium was above the level of the fluid in the pleural cavity.*

FIG. 4.—Ventrodorsal skiagram showing pneumopericardium and fluid, also pyopneumothorax. P, pericardium; Pf, fluid in pericardium; H, heart; Pn, pneumothorax; Fl, fluid in pleural cavity.

On December 24 about 100 c.c. of air were withdrawn and intrapleural tension taken at the same time and shown to be 5 mm. of mercury (equivalent to 65 + mm. of water), a mercurial manometer having been used in place of the usual water manometer attached to the

Fig. 5.—Ventrodorsal skiagram with the patient recumbent, showing fluid in the left chest with compressed lung; left diaphragm depressed. Complete outline of lower border of heart. Pneumopericardium—1¼ in. wide. P, pericardium; Pn, air and fluid in left chest; L, compressed lung; H, lower border of heart.

Floyd Robinson apparatus because of the expectation of finding a pleural tension too high for the water manometer.

On January 8 an electrocardiogram, taken by Dr. B. S. Oppenheimer, showed absence of P wave and a constant irregularity, but not the typical oscillations of auricular fibrillation. The electrocardiograms were interpreted as indicating auricular fibrillation in all probability. The R wave in lead III showed considerable variation.

On January 9, 10 c.c. of cloudy, yellowish, thin fluid were aspirated from the left chest and proved sterile, both aerobically and anaerobically. An inoculated guinea pig died subsequently of tuberculosis.

On January 18 *cardiac splash could be heard with the naked ear at a distance of* 18½ *inches from the chest wall near the apex.* On the same date there was also audible a to-and-fro sound like pericardial friction, plainest near the sternum, with the patient semi-recumbent.

On January 26 electrocardiograms showed a decided change in the heart's action since January 9. "The heart's action is regular now; the auricular wave (P) is present in every cardiac cycle. Variations in wave R have disappeared and there is now not the slightest evidence of any fibrillation of the auricles. Wave T is inverted in leads II and III."

The continued rise of fluid in the left pleural cavity gradually obscured the splash more and more and on January 28, with the fluid level in the third space in the upright position, it could only be heard when the patient was absolutely flat on his back and then up to a distance of 6 inches from the chest wall with the naked ear. On the same date both liver and spleen were palpable below the free border of the ribs, due in all probability to both enlargement and to compensatory emphysema of the right side and depression of the diaphragm on the left.

A skiagraphic plate of March 2 still showed the pres-

Fig. 6.—Patient lying on left side. Shows pneumopericardium and left pyopneumothorax. P, pericardium.

ence of a small sized pneumopericardium. Fluid hidden?

On March 5, 500 c.c. of greenish yellow pus were removed from the left chest, but on March 23 the physical signs indicated that his left pleural cavity was again full of pus to the top.

FIG. 7.—Oblique skiagram, showing much thickened pericardium with air above and fluid below pneumothorax. P, pericardium; Fl, fluid in pericardium; Pn, pneumothorax.

On March 8 an electrocardiograph showed very small waves in all three leads, indicating poor heart action.

On March 29, at a second aspiration, 2500 c.c. of purulent fluid were removed and 1300 c.c. of nitrogen substituted. Similar aspirations and substitutive nitrogen injections were made on April 19, when 2500 c.c. of thick pus were removed and 1100 c.c. of nitrogen injected; on May 20, at the fourth and last aspiration, 1850 c.c. of pus were withdrawn and 900 c.c. of nitrogen substituted. All three times, previous to aspiration, the intrapleural tension was negative.

Long before the last aspiration and nitrogen substitution, the patient had been up and about, insisting that he felt well enough, resisting all persuasion to remain in bed and even threatening to leave the hospital if his liberty were denied him.

Temperatures, which during the first month ranged between 100° and 104°, reached the normal for a few days in the sixth week, and then fluctuated during the next few months, mostly between 99° and 100.6. The original pulse range of 96 to 132 fell in March to 84 and during the month of May was continually in the 70's. The original respiration range of 28 to 36 fell to 24 in March.

The daily sputum total which originally varied between 25 and 45 c.c. dropped gradually to between 12 and 20 c.c. per day. The leucocyte count never went over 21,000 and was still 15,000 on May 15 with 76 per cent. polymorphonuclears and 24 per cent. lymphocytes.

His weight on admission was 120½ pounds, reached 128 pounds in February and was still 124 pounds on May 20 when this history was written.

The urine occasionally contained small amounts of albumin.

In spite of the comparatively favorable progress of this remarkable case, there can be no doubt of the presence of fluid and air in both the pleural and pericardial sacs. All the evidence points that way: physical signs, fluoroscopic and radiographic findings. That the fluid in the chest was pus was, of course, proven by the aspirations; that the fluid seen and heard in the pericardium was pus is only presumption, no aspiration of that cavity having been undertaken. There is no evidence indicating whether the same tuberculous lesion in the lung which caused the pyopneumothorax also caused the pneumopericardium; or, if so, where this lesion was situated; or whether a point of lessened resistance in the pericardium gave way to the pressure of the pneumothorax, causing a communication between these two serous cavities. But of the value of the *x*-ray in confirming the co-existence of these two serious lesions there can be no question. For comparison, I am appending a skiagraph of Cowan's case of spontaneous pneumopericardium and one of Wenckebach's case of artificial pneumopericardium (aspiration of tuberculous pericarditis and injection of air). The close resemblance of these two pictures to my own pneumopericardium is most striking.

Finally, I wish to draw attention to the conservative treatment of this case under circumstances where the temptation would have been irresistible for some, to have a pericardotomy and perhaps a thoracotomy, with rib resection, performed.

Merely for completeness sake I wish to refer to a statement made by James in his article on pneumothorax, in Osler's "Modern Medicine," namely, "the heart sound, occasionally have the same metallic quality as that of amphoric breathing, deriving this from the adjacent cavity." I must frankly admit

FIG. 8.—Case of Cowan. (*Quart. Jour. Med.*, Oct. 13, 1914.)

that I have never been able to confirm this finding, though in an attempt to elicit this sign or cardiac splash I recently auscultated four cases of hydropneumothorax in a great variety of positions (including knee-chest, recumbent, prone, lateral and Trendelenburg), but unsuccessfully. I also sent to thirty-six physicians with large experience throughout the country, the following query:

"1. Have you ever seen either a spontaneous or artificial pneumopericardium?

"2. Have you ever heard a splash synchronous with cardiac systole in a case of hydro- or pyopneumothorax?"

All my replies to the first question were negative. Three physicians suspected having heard cardiac splash in undoubted hydropneumothorax with no proof offered that these may not have been cases of hydropneumopericardium. The suspicion is justified that some of these cases of cardiac splash may really have been cases of complicating hydro-

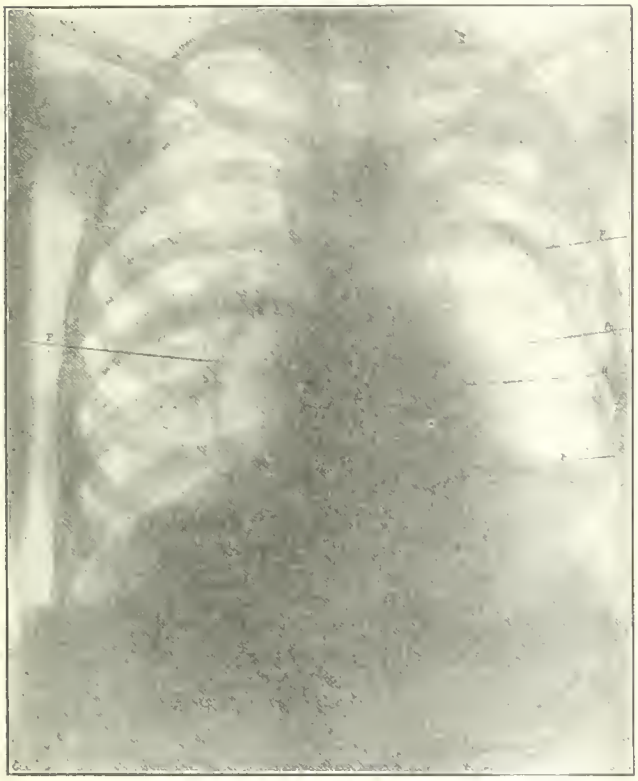

FIG. 9.—Wenckebach's case of artificial pneumopericardium. P, thickened pericardium; H, heart; Pn, air in pericardium; F, level of fluid.

pneumopericardium for whose demonstration fluoroscopy and radiography, as in my case, would have proven extremely valuable.

FINAL NOTE.—Patient left the hospital against advice on June 6, but returned three times subsequently for aspiration of his left chest. On June 15 950 c.c. of purulent fluid were removed; on July 26 1,400 c.c., and on August 27 1,300 c.c. His July weight showed a gain of 10 pounds (less 3 pounds for weight of accumulated pus?). Metallic tinkle with cardiac systole was still audible on July 22. He died in the hospital on August 28. In spite of the most earnest efforts consent for a post-mortem was refused by his relatives.

Thanks are due Drs. Jaches and Wessler of the *X*-Ray Department and to Drs. Beck and Piller of the house staff for their cooperation.

785 MADISON AVENUE.

AURICULAR FLUTTER ACCOMPANYING ACUTE ENDOPERICARDITIS.

BY SELIAN NEUHOF, M.D.,

NEW YORK.

VISITING PHYSICIAN, HAR MORIAH HOSPITAL; ADJUNCT ATTENDING PHYSICIAN, LEBANON HOSPITAL.

AURICULAR flutter is a comparatively frequent arrhythmia; up to May, 1914, Ritchie[1] collected fifty-three cases from the literature. Though it may occasionally be the result of morbid nervous influences acting upon a perfectly healthy heart, the presence of auricular flutter is usually indicative of severe disturbance of cardiac nutrition, accompanied by decompensation. The following case is, therefore, of interest because it occurred without decompensation during an attack of acute endopericarditis; after the acute inflammation had run its course, the rhythm became normal and remained so.

A. H., printer, married, aged 32, was admitted to the Lebanon Hospital (Dr. R. Stein's service) in December, 1914. He had an attack of diphtheria (?) four weeks previously for which he had received antitoxin. Data with reference to his pulse or heart at that time could not be obtained. When he entered the hospital he was suffering from polyarthritic pains and swelling, involving the heels and metatarsal joints; later the larger joints became involved. For several weeks he had irregular temperature of moderate degree. The pulse was rhythmical on admission. At the cardiac apex there was a localized dry pericardial friction rub which disappeared in two days. The patient was given salicylate of soda.

On December 8, the pulse became irregular; clinically, this appeared to be due to extrasystoles; no tracings then were taken. The next day a soft systolic murmur at the apex and again dry pericardial friction sounds were heard. The pulse and apex beat were regular. Careful scrutiny of the jugular pulsations showed no apparent abnormal activity. The electrocardiogram (Fig. 1) showed rhythmic ventricular activity at the rate of 75 per minute, but the auricles were beating regularly at the rate of 300 per minute; that is, the auricles were in a state of flutter; incomplete heart block at a four to one ratio was present. The orthodiascopic tracing revealed very slight left ventricular enlargement. There was no decompensation. On January 13, a polygraphic tracing showed that the rhythm had become normal. On January 20, the pulse was again irregular. On January 29, another electrocardiogram (Fig. 2, lead 2) showed a varying ventricular rate; most beats were approximately at the rate of 95 per minute, the extremes being 60 and 100 per minute. The auricular speed was 300. Complete heart block was present. In the third lead (Fig. 2, lead 3) the auricular rate is 280, the ventricular, 90 per minute. On February 21, tincture of digitalis in fifteen drop doses three times daily was begun in the attempt to induce first, auricular fibrillation, then, after discontinuance of the drug, the resumption of normal sequential rhythm. On March 7, after ten drachms of the tincture had been taken, the electrocardiogram (Fig. 3) showed flutter with marked irregular ventricular activity not only in speed but also in the height of the R waves. These differences were not due to the occasional superposition of auricular and ventricular waves, nor to the phasic variations in the ventricular complexes occasionally due to breathing. They were electrocardiographic evidence that the R waves, though supraventricular in origin, were following different paths in the ventricular musculature, a condition probably caused by increased ventricular irritability resulting from digitalis medication. The drug was stopped because it was assumed that any further attempt to induce auricular fibrillation would be futile. On March 28, an electrocardiogram (Fig. 4) showed normal rhythm, which was still present at the last examination. The patient has been at work for several months; there have been no rheumatic or other complaints; there was no dyspnea at any time during his illness; the evidences of a mitral regurgitant lesion and of a dry pericarditis are still present.

Auricular flutter may occasionally occur as the result of an extracardial affection. Ritchie[1] and Parkinson and Mathas[2] report cases in which nervous influences were the exciting causes. The writer saw a case in which tabacism was the etiological

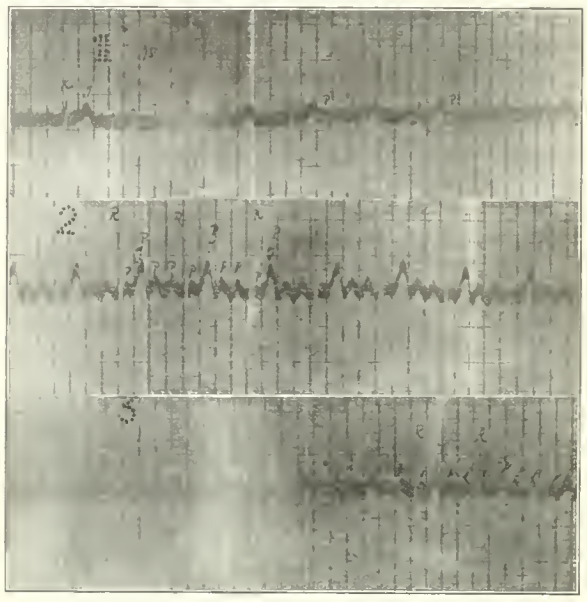

Fig. 1.—The regular rapid auricular activity is best seen in lead 3. The ventricular rate is 75, the auricular, 300 per minute; incomplete heart block is present, the ratio is 4:1. The P and T waves are occasionally superimposed. The P waves are less distinct in lead 3 and almost indistinguishable in lead 1. This is one of the characteristics of auricular flutter. In the electrocardiograms, the different leads are marked 1, 2, and 3, and refer to the direction taken by the action current of the heart. P = auricular. R — T = ventricular complex. The vertical lines measure one-fifth second.

factor. When auricular flutter occurs in cardiovascular disease, severe decompensation is the rule. It is most common in elderly people with evidence of myocarditis and arteriosclerosis,[3] and precordial pains, the latter presumably resulting from advanced coronary sclerosis. The writer has reported

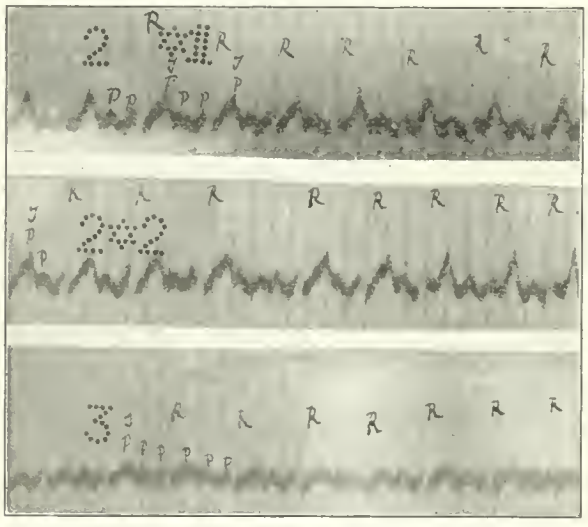

Fig. 2.—2*1 and 2*2 are different parts of the second lead. The auricular rate is 300 per minute. The ventricular rate varies; most beats are approximately 95 per minute, the extremes being 60 and 100 per minute, complete heart block is present. In lead 3, the auricular rate is 280, the ventricular, 90 per minute. For references see Fig. 1.

a case[4] in which auricular flutter was the terminal event in a young woman dying of rheumatic pancarditis.

Digitalis in our case had no effect upon the auricular rhythm, its only effect was to increase ventricular irritability. The cases of auricular flutter in which the administration of digitalis was followed by auricular fibrillation and later by resumption of the normal rhythm were those in whom cardiac decompensation was a marked feature; com-

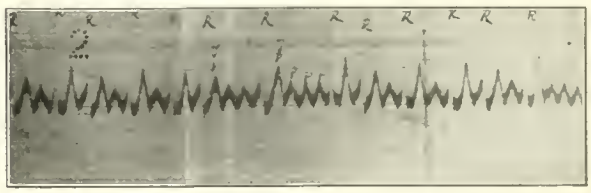

Fig. 3.—Auricular flutter with ventricular complexes varying in height and speed. For references see Fig. 1.

pensation was usually restored with the return of normal rhythm. In our case decompensation was never present, hence the beneficial effects of digitalis on the rhythm could scarcely have been expected. Sutherland[5] has described a case of rheumatic carditis without decompensation in a child in whom auricular flutter developed. Auricular flutter and the advent of endocarditis were intimately associated in the case I describe. During the time in which the rheumatic manifestations—joint involvement and fever—were present, flutter continued and was uninfluenced by medication. When these symptoms stopped, flutter ceased and the pulse became and remained rhythmical.

It is questionable whether the acute endocarditis acted by profoundly disturbing cardiac nutrition. From a careful study of the clinical course it seemed more probable that the flutter resulted from the presence of a fresh inflammatory and irritative intracardiac focus—the mitral lesion. The writer has seen several instances of auricular fibrillation—a more serious arrhythmia than flutter—which occurred in paroxysms lasting hours or days during exacerbations of endocarditis; these exacerbations were usually evidenced by the temperature, rheumatic manifestations, or change in the area and distribution of endocardial murmurs. The fibrillation ceased *pari passu* with the endocarditic exacerbations; there was never evidence of any profound or special disturbance of cardiac nutrition, no increase of decompensation or of dyspnea if already present, though, of course, each added

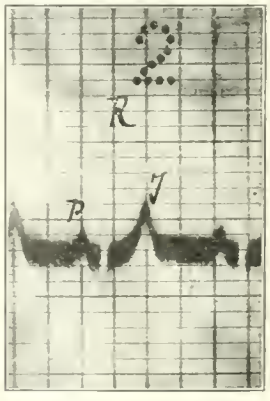

Fig. 4.—Normal rhythm, auricles and ventricles beat sequentially. For references see Fig. 1.

inflammatory focus is probably attended by a certain amount of disturbance of cardiac nutrition. The usual arrhythmias accompanying new endocarditic lesions or their exacerbations are extra systoles, tachycardias (usually simple, sometimes

paroxysmal), auricular flutter, and fibrillation. With our present knowledge we cannot individualize the special inflammatory foci which produce these special types, nor can we indicate their morbid action upon the neurogenic control of the heart.

The importance of the presence of an inflammatory endocardial focus as the cause of an arrhythmia lies in the therapy. We cannot hope to influence the arrhythmia by drugs of the digitalis group because these cannot strike at the source; in the absence of myocardial insufficiency, they seem useless. We must attempt to influence it by medication which may possibly control the endocarditis and morbid nerve influences. Such therapy is unfortunately very limited; besides rest and icebags, it comprises practically drugs of the salicylate and bromide broups, occasionally opiates; possibly in the future autogenous or other vaccines may act as curative agents.

FIVE TEASPOONS REMOVED FROM AN INTRAABDOMINAL ABSCESS AFTER PERFORATING THE SMALL INTESTINE.

BY BENJAMIN T. TILTON, M.D., F.A.C.S.,

NEW YORK.

THE surgical literature contains descriptions of many cases of foreign bodies found in the stomach and intestines, notably among the insane and children. The *x*-ray has helped enormously in the localizing of these bodies at some point in the gastrointestinal tract. It is less often that cases are reported where the foreign body has perforated the digestive tract and is discovered free in the peritoneal cavity.

The following case exhibits some unusual features of interest which make it worthy of report.

An Italian male, 32 years of age, an inmate of the Manhattan State Hospital for the Insane, began to complain September 15 last, of abdominal pain and tenderness. He was admitted to the hospital department for observation. During the week following he vomited on a few occasions, took but little nourishment and ran a temperature reaching 101° F. in the evening. Physical examination showed a very much emaciated individual with negative findings except marked tenderness and rigidity on the right side of the abdomen extending approximately from the costal margin to McBurney's point. The abdomen was flat. He stated that on August 21, a month before, he had swallowed three teaspoons and nine days later two more. In each instance he had forced the spoon down the throat, the bowl end first. The *x*-ray picture showed on the right side of the abdomen what was thought to be one large spoon. Repeated questioning of the patient invariably elicited the answer that no less than five spoons had been swallowed. A diagnosis was made of localized peritonitis or peritoneal abscess caused by perforation of the intestine, and immediate operation was advised.

Operation September 22, under ether anesthesia. A 4-inch vertical incision was made through the right rectus muscle beginning about 3 inches below the free border of the ribs. Upon opening the peritoneum a large intraabdominal mass was found occupying the region mesial to the ascending colon. This was walled off with gauze pads and opened, whereupon a large amount of pus was caught by sponges. Upon inserting the hand into the abscess cavity five spoons were found lying one upon another with the bowls at about the level of the cecum and the handles pointing upwards. The spoons were so perfectly superimposed one upon another that the *x*-ray had given the impression of one spoon. Search for the opening through which the spoons had left the intestine revealed a perforation of the jejunum close to the duodenojejunal junction which was nearly closed. The spoons were removed and two large gauze drains inserted into the cavity. The patient left the table in very poor condition but improved during the night from rectal saline injections and vigorous stimulation. The next day there was a free discharge from the wound; the abdomen was soft and not distended. Temperature 102.2°, pulse 120. The following day he had hiccough, the temperature rose gradually to 104° and the abdomen became distended. Death occurred about forty-eight hours after the operation evidently from peritoneal sepsis.

Roentgenogram showing the five spoons in the abdominal cavity; posterior view.

The most remarkable feature of the case was that the spoons were lying in almost perfect apposition, although having perforated the intestine at a point some distance from where they were found. In fact, the *x*-ray picture showed but one shadow so that the truth of the patient's statements as to the number of spoons was doubted before operation.

14 EAST FIFTY-EIGHTH STREET.

AN IDEAL NASOLARYNGEAL INHALER.

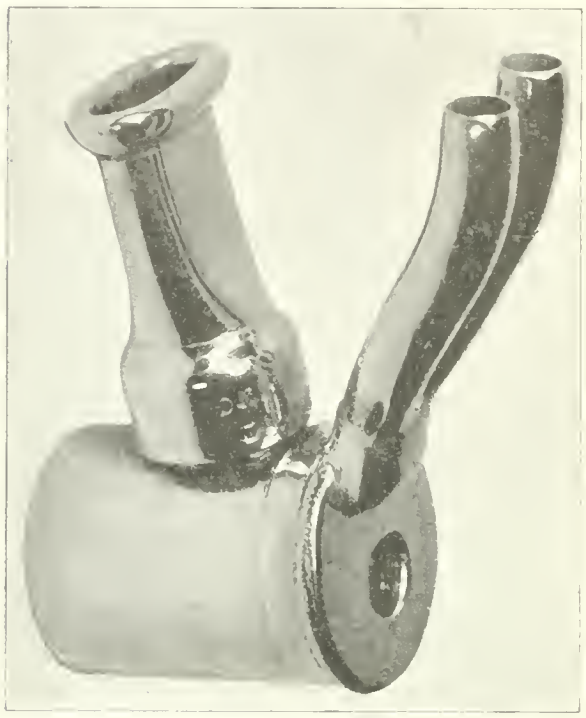
BY CHARLES E. DRESSLER AND ALFRED KAHN, M.D.,

NEW YORK.

THE instrument herewith illustrated is to be recommended because of its simple construction and the many purposes for which it may be used. The inhaler is made up chiefly of three parts; a cup, two nostril tubes, and a mouthpiece, within the cup are two minute valves of mica; one controlling the nasal tubes (allowing the air to pass smoothly through the cup, where it is purified from all dust particles and where in passing it is medicated; but the foul exhaled air from the lungs is not permitted to enter). The other valve, also of mica, controls the mouthpiece where exhaled air is permitted to pass; but the inhaled air is stopped. The instrument is held by a mouthpiece between the teeth, as shown in figure. The inhaled air passes through opening in top of cup through medicated chamber, through nasal tube to nostril—nares, postnares, pharynx, larynx, lungs. The exhaled air reverses the inhaled current and passes out through

mouthpiece, being eliminated through two holes on side of mouthpiece, and does not enter purifying chamber, through which the fresh air passes.

Its light weight and the fact that it is small enough to be carried in the pocket, give it unlimited



usefulness. The apparatus is of brass, nickel-plated, and can be boiled without taking apart.

The utility of this instrument is readily apparent: as an adjunct to office treatment, in diseases of the throat, nose, etc.; in acute laryngitis, rhinitis; in

those conditions of the upper air passages where an inhalant is indicated. It is medically cleaner and cheaper than the old-time atomizer, that is often allowed to stand around from one month to the other, that cannot be sterilized, and is used by entire families. The quantity of drug to be prescribed at a time for use in the inhaler may even be less than half an ounce. As an exercise, in correct breathing, and in those cases of mouth breathing, where all obstruction has been removed and where the mouth breathing is continued from habit the instrument has a field. This inhaler is especially recommended in acute rhinitis and the acute laryngeal conditions of winter associated with hoarseness.

34 East Fortieth Street.

THE CAUSES AND CURE OF INFECTIVE DISEASES OF THE KIDNEYS.

WITH PARTICULAR REFERENCE TO PUERPERAL NEPHRITIS.

By D. B. Mc CARTIE, M D

NEWARK, N. J.

Acute Nephritis.—Acute inflammation of the kidney is most frequently found in connection with some acute infecting disorder. This has particular reference to the infection known as scarlet fever, for in this disease more than in other infections there is apt to follow a chronic nephritis. The cause of this chronosity will be found in the presence of certain pathogenic microorganisms which are contained in urines coming from such infected kidneys; whereas in diphtheria and other contagious diseases no bacteria can be demonstrated. When the inflammation passes into the chronic stage it is probable that the irritation is kept up by the irritating properties of the urine. The damage caused by the primary irritant cannot be repaired, but every source of irritation can be lessened, thereby ameliorating the existing conditions. Another very important question is, can any other disorder outside a general infecting disease set up an acute nephritis? I think that can be answered in the affirmative. Probably tuberculosis can do so, and also any surgical sepsis severe enough to set up tubular nephritis. Puerperal nephritis is entirely of this order. The old theory of "cold" setting up acute tubular nephritis is very misleading, and cannot to-day hold any scientific basis. The kidneys are too well protected; and if "cold" ever could be a cause, it would be curious to consider why both kidneys were attacked at the same time. It is better to consider that in these cases the cause is unknown, or that it is an obvious condition easily ascertained if sought for—some surgical sepsis coming from diseased tonsils, ulcers, otitis media, tuberculosis, etc.

Puerperal Nephritis.—The cause of this infection has hitherto been unknown. It is an extraordinary fact that in such a benignant condition as pregnancy a woman should have to dread the terrifying possibility of an acute tubular nephritis. A short history of this peculiar condition will not be out of place here, but will rather add a certain interest to the study of this extraordinary phenomenon. In 1851 Frericks pointed out the close resemblance that existed between convulsions occurring in the course of Bright's disease and those which occur in pregnant women. "True eclampsia," he remarks, "occurs only in pregnant women suffering from Bright's disease: and it bears the same causal relation as convulsions in Bright's disease. It is the result of uremic intoxication, with which in its mode of manifestation it agrees."

Braun a little later supported this theory, and tried to strengthen it by means of clinical and

post-mortem observations. Even to-day the uremic theory holds its ground notwithstanding some conflicting evidence which does not fit entirely with its tenets. For instance, convulsion can occur without the presence of albumin in the urine. Such cases were set down as reflex, or epileptiform; but in such rare cases I would think that the poison acted on the cerebrum before it had time to set up acute nephritis. We see such a thing illustrated in acute septic cases of scarlet fever, where a septic meningitis destroys life before an infecting nephritis has set in. This might show that the uremia is not always the cause of convulsion, but the rule lies the other way, for we find an acute nephritis in most cases of puerperal eclampsia.

Yet in rare cases we find that the septic infection of the blood can cause convulsion before acute infection of the kidney occurs. And we know that uremia alone, without sepsis, can cause convulsions as in the later stage of Bright's disease. In such cases we understand that the causes of the uremia is chemical, not bacterial. There is a gradual shutting off of the channels of excretion, and excess of chemical poison in the blood.

Seyfert made the following observations against the uremic theory: (1) Convulsions can occur without albuminuria; (2) the albumin is due to the cause that sets up the convulsion, and is not itself the cause; (3) in fatal cases kidney lesions are not found sufficient to account for the very severe symptoms; (4) convulsions are rare where a previous albuminuria has existed; (5) in cancer of both ureters, where complete occlusion has occurred, uremic convulsions do not follow. As regards the first class, I have already spoken and observed that when convulsion occurs without albuminuria the toxin has acted on the cerebrum before it has had time to involve the kidneys.

Most observers will admit that the presence of albumin proves an inflamed state of the kidney, if we except exudations of serum albumin in dropsies, ascites, etc. But it is understood that the presence of albumin in itself is not the cause of the convulsion. There are many factors to be considered before convulsion can occur. Defective chemical excretion is sought as a cause, and yet this can happen to a very marked extent before convulsions occur. This we have noticed in the above list where the ureters were both occluded and convulsions did not happen. On the other hand, we find that certain poisons, as strychnine, staphylotoxin, etc., can readily set up convulsions, aside entirely from their action on the kidney.

In replying to the third proposition, it is contended that in fatal cases there is very little evidence left in the kidney. This is not surprising, since evidence of acute inflammation soon passes away after death.

The fourth proposition is more interesting. Seyfert claims that in cases where albuminuria already exists convulsions do not necessarily follow. In only two out of seventy cases in his observation were there convulsions. According to the theory of "renal insufficiency" all such cases would become worse as pregnancy advanced, and there would be a very high rate of mortality from convulsion, but we do not find this to be so at all. What explanation have we to offer? Certainly none as far as the uremic theory is concerned. The albumin is often markedly increased, but there seems to be little danger from general convulsions.

Finally, convulsions do not always occur though both ureters are occluded. The reason would seem to be that the system gets accustomed to poisonous chemical products when the obstruction is of slow development, but in acute nephritis, due to bacterial infection, the poisoning of the blood is rapid and convulsions occur readily, whether the cause be found in bacterial or chemical disturbance.

The Traube-Rosenstein Theory.—This theory held its ground for some time. It consisted in a condition called hydremia, caused by the loss of albumin from the blood. This condition brought about increased arterial tension and edema of the brain. Compression of the blood vessels occurred producing coma and convulsion. The slight increase of the blood pressure during the labor pains gave zest to this idea, until some time later Spiegelberg entirely disproved such a vague hypothesis.

McDonald's Theory.—His idea was that anemia of the brain is caused by vasomotor irritation, which irritation is a manifestation that the kidneys are defective, and therefore unable to deplete the blood of poisonous elements. Other attempts have been made in the same direction to try and prove that peripheral irritation causes convulsions. There was reason for this because two-thirds of all cases occurred during labor. Any source of irritation at this time, such as removal of the placenta, examination of the patient, etc., would often lead to convulsions. Even to-day there are theories formed around this preconceived notion. It seems the liver is "insufficient" as well as the kidney. The thyroid is spoken of since there is some enlargement of that gland in pregnancy. Other signs of "insufficiency" are general arterial tension, headache, neuralgia, etc. A blood count is taken, the fundus of the eye is watched, lumbar puncture and even decapsulation of the kidney are suggested as a cure for the supposed renal "insufficiency." A late text-book dealing with this subject says: "The toxemia of the second half of pregnancy is supposed to be due to a failure of the maternal organism to excrete both its own and the waste products of the fetus. These waste products are disposed of partly by the liver, being broken up by oxidation into substances which can be eliminated; therefore it is evident that if the kidneys or the liver are insufficient, there will be an accumulation of toxin in the blood." Yet with all this theorizing no attempt is made to explain what this "insufficiency" of the kidney or liver means. It would be a singular fact to find one woman's kidneys or liver more "insufficient" than another's. In the case of twins there should be undoubted "insufficiency," but there is not. It also happens that a woman who was eclamptic with her first child may not even be the subject of a simple albuminuria with her second. It is also a common fact to find the urine normal within a week or two before labor, whereas if faulty elimination were the cause of albuminuria we would expect to find a gradually increasing quantity of albumin as the child grew larger, but this is not the case at all. Again we would find "insufficiency" of the kidneys most common in weaklings and in debilitated women, whereas it is precisely the contrary that happens, for we find it mostly in the healthy and robust patient. Finally, we would expect to get marked "insufficiency" in all cases where a previous albuminuria occurred, yet in such cases, according to Seyfert, only two out of seventy suffered from convulsion.

The following are some case reports of albuminuria in pregnancy:

Case I.—Mrs. P., primipara, age 36, of robust constitution. No albumin appeared in the urine until two weeks before the birth of the child. The conditions became so serious that premature delivery was brought on two weeks before the expected time. On December 20 the urine was normal. On January 1 an immense quantity of albumin was present. The child was born by the breech, and was almost in the world when the first spasm occurred. The patient died one week later in coma. This case illustrates that albumin may be found in the urine at any time in pregnancy, and that it may occur with extreme suddenness, and in very great quantities.

Case II.—Mrs. McD., primipara, age 19. Always in good health. Urine normal until four weeks before birth. About this time on account of cramps in the left leg her husband rubbed the leg with rancid oil, setting up a severe dermatitis. While the limb was still very sore and swollen albumin appeared in the urine, and numerous colonies of microorganisms were seen in the microscopic field. It was not, however, a case of puerperal infection. Infection of the amniotic sac did not occur. The case came under the heading of surgical infection, and as soon as the local source of infection in the leg was removed the urine again became normal. There was no trace of albumin at the time of birth. I report this case since we may mistake such a condition for infection of the amniotic sac, thereby causing unnecessary fear to a pregnant patient.

Case III.—Mrs. L., multipara, age 26. Generally of good health. At the sixth month albumin was found in the urine. The amount of albumin increased slowly and then remained stationary for several weeks. Under treatment albumin disappeared gradually and the urine was normal several weeks before the birth. After treatment was once established the case resembled one in which the child is already born, that is, the albumin began to get less and less until it entirely disappeared. With the disappearance of the albumin the dropsy, headache, vomiting, etc., also improved. This was the first case in which I tried the antiseptic treatment and was rewarded with very brilliant results. Against all ordinary rules, instead of a continued increase in the albumin there was a steady decline until a normal state of things was established.

Case IV.—Mrs. A., 30 years, primipara, apparently healthy before marriage. Albumin appeared in the urine only four weeks before the birth of the baby. It became so serious that premature birth was brought on. The child was born naturally. No convulsions occurred, but after the birth albumin still continued in the urine, not the customary few weeks, but for months. In fact a chronic albuminuria was established.

I feel sure that the urine was normal for several months in the earlier part of the pregnancy, and I can only imagine that all cases of puerperal nephritis do not clear up after the birth, but may become chronic, as after scarlet fever. Happily this is not the usual condition, but it may be well to remember that such a thing can happen, and in so far as we can stay the course of an acute nephritis we can thereby eliminate the dangers of a chronic kidney disease.

The Cause of Puerperal Nephritis.—The cause of infection of the kidneys in pregnancy is probably due to infections of the amniotic sac. This infection probably starts from a local cause, a septic discharge from the vagina being the most common source. Any septic condition at or near the cervix uteri can lead to infection of the amniotic sac. We might call the condition one of absorption or osmosis. Microorganisms are not generally found in the liquor amnii, yet the toxic products of bacteria from the vagina are most certainly the cause of this infection. As the os uteri becomes more and more patulous, as in the later stages of pregnancy, the danger of infection becomes greater. We know that the liability to infection is greater in primiparæ; probably the reason is that the canal retains the infecting materials better, the os being torn in multiparæ so that septic discharges would not be retained so effectively.

Septic conditions in the vaginal canal can occur in several ways: Putrefaction of vaginal secretions; contamination through soiled clothing or any other external source of infection; infection from within from septic conditions in the bladder, and infections which come through the male, which is the most likely of all to carry septic material to these parts. We should, therefore, warn all pregnant women of the dangers of such infections, and point out to them the remedy which, of course, consists of surgical cleanliness, this rule applying as much to the male as the female. If a septic discharge occurs we ought to advise thorough vaginal douching, several times daily till the source of the contagion is removed; this is particularly so when albumin has appeared in the urine. A septic vaginal discharge is always associated with infection of the kidneys and albuminuria. Antiseptic douching can do very little harm and may accomplish a vast amount of good. The water ought to be about body temperature, and any antiseptic can be chosen to suit the case. The albumin will be found to disappear slowly, as in a case where the child is already born.

The day is not far distant when every pregnant woman will be ordered to use an antiseptic douche. Microscopical examinations of vaginal discharges ought to be also frequently made. The liquor amnii ought also to be examined, although septic germs are not always found in it even when marked infection of the kidneys and convulsions have occurred. The poison is more of a toxin than the mere presence of a germ, but the liquor amnii itself does readily decompose showing almost the same microorganisms at all times, in marked contrast to the urine (with the exception of the *Bacillus urinæ*) where no uniform conditions are found.

Interstitial Nephritis.—It is most likely that interstitial nephritis is a type of renal inflammation or irritation in a class by itself. It is identical with cirrhotic processes elsewhere, that is there is a marked tendency for the connecting tissues to suffer most, if not exclusively; the other conditions being secondary to contraction of the new-formed muscular tissues. The irritant probably reaches the intertubular tissues through the nutrient blood-vessels, whereas in acute nephritis the poison is carried to the tubules themselves. It would be better to try and differentiate one class entirely from the other. The increase of connective tissue constitutes the most prominent feature of chronic Bright's disease, known as Bright's disease with contracting kidney. The onset is generally insidious, with increased secretion of urine, absence of dropsy, and only faint traces of albumin. In the first stage of the disease the tubules are unaffected, which shows that the first change really occurs in the intertubular tissues, and later when the tubules are affected it is more the result of constriction from this hyperplasia than from any disorder in the tubes themselves. The walls of the blood-vessels are thickened due to hypertrophy of the muscular coat which appears to be continuous with the newly-formed tissue between the tubules. The resiliency of the vessels is interfered with and the blood-pressure is as a consequence very much increased. Similar changes occur in small capillaries all over the body, but they would appear to have their starting point in the kidney. So we would consider that any chronic irritation capable of setting up interstitial ne-

phritis can also set up similar changes in the blood-vessels of the body. Such a source of irritation will be found in chronic forms of malaria, probably in rheumatism, in syphilis, in gout with repeated attacks and pus in the joints, and in any chronic process where the suppuration is so to speak external, and too much pus does not invade the blood current, but where there is none the less a certain absorption of septic discharges. This we find commonly in rectal fistula, otitis media, onychia, septic conditions of the nose and throat, repeated attacks of tonsilitis, probably also chronic enlargement of glands, iritis, gastric ulcer, gall-stone infection, etc. In tuberculosis a tubular nephritis is more apt to occur. There cannot be a continued inflammation without a continued cause, so in every case of interstitial inflammation it is imperative for us to seek the cause. The greatest difficulty, however, will be found in the fact that the disease has existed for many years, and that it was not until some noticeable symptom had driven the patient to the physician that such a disorder was even suspected. But the chief reason for this disease getting ahead of the physician lies in the fact that the usual chemical tests are entirely fallacious. No trust should be placed on Heller's test when small traces of albumin are sought for. Heat with weak acetic acid is the only reliable test. It is about time to abandon the Heller test, which is entirely misleading in the presence of small traces of albumin. In using the heat test, which is very accurate, the urine ought always to be filtered. This is essential to get a good result. It is best to heat the top layer of the tube in the usual way, and then view it through a good light, placing some dark object behind as a better contrast to the whitish cloud of precipitated albumin.

The blood-pressure in interstitial nephritis is higher than in any other disease and is a more permanent factor in this disorder. We might ask the question, why does not the blood-pressure increase in other cirrhotic processes, as in cirrhosis of the liver? We can give no definite answer except to say that in one disease the process is more localized than in the other. The heart action is not affected as much in cirrhosis of the liver as in cirrhosis of the kidney, and the other vessels do not become cirrhotic. It appears to be the case that the poisons which can circulate in the blood in cases of syphilis, malaria, gouty and rheumatic conditions, imperfect drainage from small suppurating cavities, as fistula, gallstones, etc., do set up this interstitial change in the kidney. Alcohol is probably modified by the blood current and does not act directly on the kidney. It is problematical whether spicy foods, or heriditary conditions can ever set up a chronic interstitial nephritis.

Albuminuria.—There are so many tests for albumin in the urine that it would be useless to enumerate them here. They are mostly qualitative; what the medical man wants is a sure and quick method of determining the presence of serum albumin in the urine, but at the same time it would be an advantage to him if he could determine the quantity even roughly. A modified Heller test is good for this purpose. I use a long graduated tube with a firm stand, marked off in parts of a cubic centimeter. The nitric acid is used in the usual way, and the urine is allowed to drain down the side of the vessel. The quantity of albumin is then read off in parts of a c.c.. It is best to heat the urine first and, as before said, to filter before making the test. Traces of albumin will not respond to this test, so in dealing with cases of interstitial nephritis no trust should be put in Heller's test.

The gravimetric method or weighing of precipitated albumin is the only exact means we have for determining the quantity of albumin in a given sample of the urine. A brief allusion to this method may not be out of place. It is based on the well-known fact that heat coagulates albumin. Then if we are particular not to count in other coagulable ingredients in the urine we are certain to get a correct estimation of the quantity of albumin in a fixed quantity of the urine. Take 20 c.c., dilute with 80 parts water; heat over a water bath half hour at 100°; add a few drops of acetic acid to further coagulation; filter, dry, and weigh. Too much acetic acid redissolves part of the albumin, and in alkaline solutions an alkaline albuminate is formed that does not coagulate on heating.

Albumin can also be coagulated by alcohol, carbolic acid, or tannin, and can then be filtered, dried, and weighed. Albumin is not precipitated in alkaline urine. Albumin does not act in dialysis in the same way as the serum of the blood. Albumin is different in different stages of Bright's disease, and is also different in temporary albuminuria. Paralbumin precipitated by alcohol redissolves in large quantities of water. In Bright's disease the alcoholic precipitate does not redissolve in water. Peptone can be precipitated from urine by alcohol after the other varieties of albumin are coagulated by heat. Five grams of albumin excreted in 24 hours is an insignificant amount; 6 to 8 grams moderate, 10 to 12 considerable. There is no serious drain on the system with an average loss of albumin if the nutrition is kept up, except in fevers where the digestion is poor, since three ounces of meat daily will make up for the loss of ten grams of albumin.

The heat and acetic acid test is very reliable for small traces of albumin. The Heller test, as has been said, is not to be relied on where small quantities are present, and almost all cases of interstitial nephritis will be set down as normal according to the Heller test.

Bacteria in the Urine.—Naturally there is no such thing as urine entirely free from bacteria, yet certain forms are found only in connection with certain conditions. So we find commonly: (1) Chains of streptococci, large and small, due to cystitis, probably originating in a vaginitis. (2) Staphylococci from the same source. (3) *Bacillus urinæ* found in all stale urines. (4) Very fine streptococci in twos and threes or in single cells, found in the urine after nephritis due to scarlet fever.

In studying the urine coming from different disorders we find distinct differences according to the disease. In minor surgical conditions we generally find small chains of streptococci, always faint and indistinct, in chains of twos and threes. Staphylococcic groups I have never seen. We sometimes find a similar condition after diphtheria, but as a rule the urine is free from bacteria. This is very different from scarlet fever, in which innumerable colonies of bacteria are always present at some time after the appearance of the albumin. In stale urine no matter what the disorder we always find a large bacillus of dumbell shape. It becomes evident in about 24 hours, the time when the alkaline change occurs in the urine, and is probably connected with this chemical condition. In urines

coming from chronically inflamed kidneys there are no specific germs or bacteria found. Of course bacteria will develop if the bottle is not sterile, but we never find the same characteristic bacilli as after scarlet fever, or even in minor surgical conditions. By these I mean septic conditions of the skin, of the fingers, an otitis media, a rectal fistula, a chronic catarrh, a gallstone infection, a gastric ulcer, etc. Septic germs will appear in the urine as long as the cause is present, but they will soon disappear, as will also the albuminuria, when the septic cause is removed. The liquor amnion is singularly free from germ life, even in infected cases, though very liable to decomposition soon after being exposed to the air. For staining urine-smears a very weak solution of methyl violet is best. Methylene blue is too thick and is apt to become sticky, whereas methyl violet spreads evenly and stains well in the very weakest watery solutions.

Arterial Fibrosis.—This condition is probably brought about in two ways: either by stasis in the kidneys, or by the action of a general poison on the vessels themselves. Nature sets out to overcome the blocking of the tubules which the inflammatory disease sets up. The convoluted and extensive mass of tubules are seriously obstructed by the process of inflammatory products, and there seems to be no other way on Nature's part to relieve this condition except by excessive pressure on the part of the heart and blood-vessels. In acute cases recovery takes place in a few weeks, but in chronic cases the resistance continues with the very unfortunate results which we find in the small arteries in almost any part of the system. There may be also a chemical or bacterial element behind this process, as in malaria and syphilis, but at present it is impossible to say how much the process is due to mere mechanical action or to chemical or bacterial irritation.

Prognosis.—In all chronic subinflammatory diseases of the kidneys the prognosis is bad if we cannot remove the cause. The prognosis may be guided by the microscopic findings. In cases due to minor surgical infections the patient will get well if the infection is removed. In malarial cases a cure ought to be obtained, also in those caused by syphilis. Minor surgical infections should receive careful study. Attempts should be made to cure fistula, gallstone, gastric ulcer, recurring tonsillitis, otitis media, skin infections, and all sources of such irritations should be carefully sought for and cured if possible without delay. In acute nephritis the disease is serious or not, according to the infection which set it up. Most patients recover after measles, diphtheria, septic surgical conditions, but in many cases the disease becomes chronic after scarlet fever. Pregnant cases rarely become chronic. In some cases of diphtheria the urine will be normal for several days and then show traces of albumin. In scarlet fever microorganisms will always be found in the urine; when they disappear the prognosis is good, otherwise a chronic inflammatory process will set in. As scarlet fever is the one disease most likely to set up a chronic tubular nephritis, chemical and microscopical examinations ought to be made frequently and for months in any case of this disease.

Treatment.—In all acute infections we must endeavor to protect the kidneys from infection. This is difficult to do if the blood-current is invaded by the microorganism which set up the disease. We should also try and check the growth of such organisms at their site in the throat with some better ideas and means of prevention than have hitherto been in use. It is probably useless to try and disinfect the throat by a few gargles of some harmless antiseptic, or some mild sprays for the same purpose. Here it would be better to strike at the root of the disease by some more radical method. Painting the tonsils and throat hourly with some strong disinfectant, as carbolic acid or bichloride of mercury, should be tried in as strong solutions as we use for other disinfecting purposes. The application of antiseptic powders to the throat by means of a brush should also be tried, those best to use being salicylic acid, boric acid, chlorate of potassium. If notwithstanding the local attempts at disinfection in the throat and nose, an infection of the blood has occurred it might be well to try internal antisepsis as far as any good may accrue from such methods. Small quantities of mercury may be given, as any salt of this is highly antiseptic in the blood-current. Arsenic has much the same effect. Salicylic acid is probably the best in scarlet fever. When the kidneys are infected we might still try antisepsis in a urinary form and make use of drugs supposed to have such an effect on the urine, such as salol, hexamethylenamine, etc.

In chronic cases of tubular nephritis a continuation of the antiseptic treatment to a certain point may be still good treatment, but after a time all irritating drugs should be omitted, and this means almost every drug in the pharmacopœia. Drugs irritate, and it may be better to omit them altogether, except some mild salines which dilute the urine and render it less acid, thereby diminishing its irritating qualities. One drug also gives good results, and that drug is digitalis. It equalizes the defective circulation in the kidney, and helps Nature's process at curing the condition, which is to strengthen the heart and thereby force the blood through the obstructed organ. Diet may be of some importance—a light diet is best, but we know that three ounces of meat diet will make up the loss of ten grams of albumin daily; it is therefore better to supply a necessary amount of meat diet to keep up the balance of the nutrient properties in the blood. Mineral purgatives give good results because they keep the bowels open and are also alkaline. I would not advise iodides as a panacea even for arterial fibrosis except in cases with a complete syphilitic history. It seems to me that we ought to be very conservative in regard to our remedies, and not discard the older and well-tried medicines for some newfangled ideas which sound well but which rest on no certain scientific basis in the present state of our knowledge. However, in kidney disease the very first law is to avoid irritation, either by diet, by drug, or other injudicious treatment. Our purpose is to conserve the secreting cells and not to irritate them, therefore it would be safer for a man to avoid drugs altogether than to take chances that any special drug will irritate his kidneys. In chronic tubularnephritis warm baths are to be commended to aid the skin in its function as a diuresis. Light salines may be of advantage in the form of lemonade, cream of tartar mixture, oranges, and mucilaginous drinks. The urine being an acid fluid acts as an irritant on the inflamed tubules and anything that dilutes the urine and renders it less acid thereby aids in preventing irritation. High sp. gr. would argue increased irritation as we see in fevers with a high temperature. The acidity of normal urine is supposed to be caused by the acid salt sodium phos-

phate. There is little free acid, if any, but some chemists maintain that the acidity may come from uric, hippuric, or carbonic acids. This acid reaction may be modified or lost in two ways. After the urine is passed urea is changed into ammonium carbonate by the absorption of water. This conversion of urea into ammonium carbonate was thought previously to be due to the action of a ferment, but now it is known to be bacterial. This conversion of the urea occurring in the urinary passages would cause great irritation, but it is rarely met with in kidney disease. Normal alkalinity of urine occurs in 24 hours after being passed—a glass rod moistened with HCl held over the urine will give forth clouds of ammonium chloride.

Secondly, the reaction of the urine may be changed by the condition of the blood. This is indeed a highly important matter when dealing with a case of chronic nephritis, for we can modify the urine as it passes through the diseased tubules and thereby prevent irritation. Under normal conditions acid urine is formed from alkaline blood—the kidneys having the power to extract acid salts from the blood, yet when the blood is highly alkaline acid urine is no longer secreted. It becomes neutral when large quantities of alkalies are introduced into the blood currents. Such are the carbonates of lime, potash, magnesia, also vegetable salts which are changed into carbonates in the body, and excreted as such in the urine, the citrates, the malates, the acetates. According to Bence Jones, 20 grains of tartrate of potash in water will cause alkalinity of the urine in thiry-five minutes. Foods act in the same way. In carnivorous animals the urine is strongly acid; in herbiverous it is alkaline. Jones also pointed out that the acid reaction of the urine increased inversely with the secretion of the gastric juice. The urine is most acid at night, and least so before noon. After severe exercise the urine is also very acid, as if the waste products of muscular disintegration caused an increased acidity in the urine. Very acid states of the urine favor crystallization, thereby favoring irritation. The question of the exclusion of the chlorides may be answered this way:

1. In all acute febrile diseases the amount of chlorine eliminated diminishes rapidly. As recovery progresses, it increases. This is probably due to the digestion and the meager diet. In intermittent fever there is no marked diminution, probably because the patient eats well between the attacks of the fever.

2. In chronic diseases the elimination of chlorine is subject to great variations. As a rule it is diminished. In diabetes the chlorine appears to be increased. In dropsies there is also an increase when diuresis begins. Excess of sodium chloride may be injurious by preventing blood formation and by displacing albumin. The amount of chlorine is of importance to the physician in all chronic diseases, since it is a good measure of the digestive powers of the patient. An excretion of 6 to 8 grams daily gives evidence of a fair digestion. We can see from these facts that an excess of chlorine may be harmful in chronic kidney diseases, but the question is whether a small quantity, such as is likely to occur in the poor digestion of patients with Bright's disease, can be any way irritating to inflamed organs. While it will probably be wise to moderate the ingestion of salt, it might not be well for the health of the whole body to eliminate it altogether.

In dealing with kidney disorders, we must therefore prevent all acute infection and modify chronic disease by stopping all sources of irritation. In acute eclamptic attacks little can be accomplished by drugs. The issue will depend on the state of the kidneys and the quantity of uremic or bacterial toxins in the blood. We try and attempt elimination by baths or purges, but it is far better to prevent the acute attack by watching the urine, the quantity of albumin secreted being a fair indication for our treatment, and if this should persistently increase under treatment, as I have outlined, it would be fairer and better to our female patients to terminate the pregnancy than take risk of an eclamptic condition.

The reason why in two-thirds of all cases of ecclampsia the spasms occur during labor will be found in the fact that the uterine contractions cause a forced absorption of the septic liquor amnii into the blood.

93 Fourth Avenue.

A REVIEW OF THE STUDY OF THE PSYCHOSES ASSOCIATED WITH CEREBRAL ARTERIOSCLEROSIS.

By JOSEPH NACK, M.D.,

WASHINGTON, D. C.

GOVERNMENT HOSPITAL FOR THE INSANE.

Osler says: "Modern life favors the development of arteriosclerosis, as a man is apt to work his body machine at high pressure. In the fourth and fifth decades of life, even with the best of habits, the incessant drain and anxiety of public life and business may lead to arterial degeneration. The mental exertion that goes with our present business and professional life, with its stimulating environment, and with such keen competition, even without social or political ambition makes high mental pressure a necessity. The tragedies of life are arterial; represented in old mythology as Winged Nemesis, the Goddess of the Inevitable may still be pictured with a wheel—the Wheel of Life, the ceaseless revolutions of which the circulation administers. How often does the fatal touch call away in their prime the best and the bravest. Living quieter lives, with less strain and stress, women are less affected with this disease."

Etiological Factors.—It is said by most authorities that arteriosclerosis is common during the seventh decade of life. Kraepelin has found cases with evidence of arteriosclerosis as early as the fourth decade of life. It may be that in those cases of premature arteriosclerosis an early and perhaps inherited tendency exists for this disease. This is seen where one or more members of the same family show evidence of the disease early in life, but show no mental disturbances; but if excessive demands are made on the nervous system the patient may develop an early cerebral arteriosclerosis. Romberg well puts it when he states that arteriosclerosis is always severe in that part of the body where vessels have undergone the greatest strain.

From a histological standpoint Aschoff says that, following the period of complete development of elastic fibers in the tunica intima of the arterial wall, there succeeds a period during which the vessels remain histologically unchanged. This period extends to the middle or end of the fourth decade of life, then follows the descending period of life of the arteries, which is characterized by senile

sclerosis. Another etiological factor is chronic alcoholism, and Kraepelin states that it especially favors the development of a disseminated sclerosis of finer blood-vessels. Chronic intoxications, as lead and arsenic poisoning, chronic intestinal stasis, chronic malarial intoxications may also be causative factors. A most prolific cause is syphilis, especially the acquired form. Certain metabolic diseases, as gout or diabetes, may be factors in producing arterial sclerosis. Continued great physical exertion is also a factor. Individuals inclined to emotional outbreaks and who live under constant strain and excitement are liable to develop cerebral arteriosclerosis. States of continued anxiety and especially where responsibilities are great, as often seen in physicians, legislators, brokers, merchants, financiers, army officers, and in chronically worried individuals, are likely to develop the disease.

To summarize, we have: (1) The involutionary period, in which degeneration is caused by ordinary wear and tear of life, which is as natural as gray hair and failing eyesight. (2) The toxic group in which degeneration is caused by poisons of acute and chronic infections and intoxications, alcohol, etc. (3) The hyperpietic group, in which degeneration follows persistent high blood pressure.

The consequences of the effects of arteriosclerosis on the mental functions are of great importance, and we shall briefly review them.

Arterioslerosis plays an important rôle in the life of the heart, the kidneys, digestive system, and especially the highly sensitive nervous system. Like every other organ, the part of the nervous system which is the organ of mental functions has its distinct biotrophy or vital elasticity characteristic of the individual, and often enough it ages in many members of the same family more or less independently, and it may suffer through arteriosclerosis in three directions: (1) From effects of reduction or change of metabolism due to arteriosclerosis of some other organ, *e. g.* heart and kidneys; (2) from disease of its own vascular mechanism, especially sclerosis of larger or smaller vessels of brain; (3) or it may run behind in its own metabolism, owing to exhaustion of vital elasticity, of nerve tissue proper, especially when more trying demands are made upon it, through toxic substances, *e. g.* syphilis and alcoholism or stress and anxiety of life.

These factors should be considered in a diagnosis, if by diagnosis we understand not a mere name, but a statement concerning the nature of the disease, the causes and their working, and possible clues concerning means of repair.

Alzheimer has described four varieties of the disease, which are to an extent differentiated clinically:

1. *Arteriosclerotic Brain Atrophy.*—This occurs in two forms: The mild form with severe arteriosclerosis, but absence of focal brain lesions; symptoms are easy fatigue, slight failure of memory, dizziness, and headache. The severe type may resemble the mild type at first, but is progressive and leads to profound impairment of cerebration and presents in its course epileptiform and apoplectiform attacks and focal symptoms.

2. *Subcortical Encephalitis of Binswager.*—In this condition the white matter of the brain is largely involved as a result of the disease in the long medullary arteries. Epileptiform and apoplectiform attacks occur, also transitory attacks of confusion, aphasia, and paresis, disturbances suggesting focal lesions. Focal lesions are not found extensively, but areas of softening often occur in basal ganglia.

3. *Perivascular Gliosis.*—In this condition there is a disappearance of nervous elements about the diseased vessels and replacement by neuroglia.

4. *Senile Cortical Devastation.*—We find extensive destruction of cortical areas in vascular territories of diseased vessels.

Pick has very thoroughly described certain large atrophies involving whole lobes or portions of lobes. The occipital lobes may be involved producing blindness, or the temporal lobes producing deafness. The atrophy does not always follow a vascular atrophy and so while it is generally supposed to be due to arteriosclerotic disturbances in the irrigation of these territories, the cause is not always clear.

The basis of arteriosclerotic mental disturbances is not so much the general softening and destruction of cortical fibers, as the more diffuse condition of the cicatrix-like alterations and changes at various points.

It must be borne in mind that symptoms in any given case usually afford only a rather vague basis of the exact localization of the cerebral changes. It is questionable whether one is able to separate clinically an arteriosclerotic perivascular gliosis from cortical devastation due to the same cause. In considering a case, seek first to determine the amount of damage which the brain has suffered; localization is more or less secondary.

Let us consider the forms of insanity occurring after the age of 45, and ask in which we have reasons to suspect cerebral arteriosclerosis.

First we meet with all these forms which may occur at any age—alcoholic psychosis, general paresis. Further, exhaustion deliria and that group of patients who have a number of attacks in their life, usually depressive or exalted or mixed (*i.e.* manic-depressive psychosis). Further, forms of paranoid or delusional states and forms of deterioration.

As specially characteristic of that period we find anxious melancholia and certain paranoid states of hypochondriacal disturbances. We know that they may occur without arteriosclerosis.

The specifically senile psychosis is practically always associated with some arteriosclerosis; it is, however, one of general mental reduction and apparently is a fairly independent condition. Senile reduction of mind is a phenomenon from which few people escape completely in old age, and which is apt to show prematurely in some individuals. This is usually part of general senile reduction.

In ordinary life we notice decrease in memory, tendency to follow ruts of thoughts, and to rehearse them, a certain narrowing down in interests and in the grasp of new things.

Well founded suspicion of arteriosclerosis exists, however, when an ominous deterioration begins, with gradual loss of memory, narrowing of judgment, and transitory states of confusion, without the cardinal symptoms of general paresis.

Loss of memory which affects the most recent past events makes the patient repeat himself, he gets confused temporarily, and especially at night is unable to locate himself, and is apt to develop outbreaks of anxiety, often with frightful hallucinations. At times gaps of memory are made up for very liberally by confabulations. Patient does not remember what time of day it is, but says he

has been to town, etc. Frequently shows aimless desire for activity. Not infrequently the delirious states are transitory at first, chiefly nocturnal, whereas the fundamental defect of memory and judgment, which is not accounted for by temporary confusion and perplexity, is as a rule lasting or progressive. Often we see increasing self-absorption with hypochondriacal complaints, partially built on natural fear of becoming unable to control sphincters; the patient claims that internal organs are absent, bowels stopped up; a feeling of helplessness leads to ideas of persecution. To what extent cerebral arteriosclerosis, as such, is actually the cause or simply a part of general involution is one hard to decide definitely. After all, the only symptoms which can be laid more directly to changes in blood-vessels are those of focal nature, of various extents, the appearance of symptoms of focal lesions in the brain, and vague symptoms, such as circulatory difficulties, dizziness, occasional occipital neuralgia, or even neuralgia of a whole side of the body. Are we justified at present in speaking of arteriosclerotic psychosis as a disease entity or only of a psychosis of senile or premature senile involution, and is it true that the real arteriosclerotic nature is revealed only by the cause, by nervous and collateral symptoms of focalized or general arteriosclersosis?

The so-called organic dementia, following apoplexy, is usually a compound of the effects of direct focal destruction and diffuse changes. In rare cases, though, it would seem as if focal lesions as such might cause transitory mental disorder. But these cases are difficult to analyze and one should be careful with the statement frequently made that a little "hemorrhage" or "embolism" is the cause of transitory mental disorder.

As a rule the weight of the brain is very much reduced in old age. This reduction keeps pace with the "dementia" so that in simpler delusional forms and in many cases of senile melancholia the weight of the brain is said to be relatively high, whereas actual dementia is accompanied by fairly parallel loss of weight. In many cases atrophy refers more particularly to special localities, such as the temporal lobe, without there being any focal lesion whatever. The nature of blocking of circulation or softening we can obtain from fairly pure symptom-complexes of aphasia, in such cases with local atrophy. Even in these cases it is not always easy to demonstrate a parallelism between the atrophy of the part and the condition of the blood-vessel feeding it. It is impossible to draw a line between cases of simple atrophy of the brain and those of atrophy with focal lesions, except where lesions implicate a part which we can recognize by its focal symptoms during life. In other words, the vascular nature of dementia can be diagnosed only by the existence of distinctly vascular symptoms. As a rule vascular lesions affect the chief vessels of the base and at times the disease process extends to smaller branches and very diffuse changes are possible, such as a small multiple aneurysm, not only in place of predeliction (internal capsule) but in various parts of cortex.

The course of the disease is either progressive, the mental loss becoming more profound as time goes by, or mental deterioration may come to a standstill. During the course of the disease there is a peculiar variability in the intensity of the symptoms at different periods. How long a patient may live it is difficult to say. Death may come quickly or be long deferred, even for years. Intercurrent infections, pneumonia, uremia, etc., may carry off the patient. Severe apoplectic strokes may cause death, or the case may go on to a terminal state resembling to a great degree other organic dementias.

Diagnosis.—Neurasthenia is frequently diagnosed in men past the fifth decade or even in the early sixties, the symptoms as a rule being irritability, insomnia, headache, defective memory, and personal inefficiency. The previous history is to be gone into carefully to note onset and cause, if such can be found. It should be remembered that sclerotic changes are apt to occur early in neurasthenics, whether it be of the acquired or constitutional type. From paresis a positive Wassermann in blood shows that we are dealing with a syphilitic patient. Sclerosis of vessels is common in them and may occur early in the disease. An examination of cerebrospinal fluid when possible and with increased globulin content and increase in number of cells in fluid, and Langs-Gold test is diagnostic of paresis. In simple sclerotic conditions the fluid will be negative, even if the blood reaction is double plus. An increase in albumin content is not rare in severe arteriosclerosis, but is usually less than in luetic diseases. A pleocytosis is also very rare in purely sclerotic conditions, and while it has been reported is of no practical value in deciding whether the sclerosis is or is not due to lues.

In differentiating between syphilitic brain disease and arteriosclerotic mental disturbances, pupillary reactions are important and also fundus examinations for sclerosed retinal arteries. In cerebral syphilis an Argyll-Robertson pupil is usually found, that is, loss of light reaction, but reaction to accommodation is retained. Also examinations of blood for Wassermann test and examination of cerebrospinal fluid for pleocytosis and globulin increase.

In paresis pupillary signs are usually stationary, while in sclerosis pupillary signs may change on different examinations. They may react; another day do not. The changeableness of pupillary reaction in sclerotics is often seen. In paresis such changeable conditions of pupils do not occur. Also if pupils are affected in cerebral arteriosclerotics both light and accommodation are affected. In arteriosclerotic conditions the speech is not characteristic. There may be some difficulty in saying the test phrases, but in paresis there is marked disturbance in speech, fine tremor of lips. Paresis usually occurs between the years of 30 and 40, and may occur earlier. Arteriosclerotic mental disturbances usually occur after the fifth decade of life and are most pronounced in the sixth and seventh decades. Focal signs of organic brain injury and permanent paralytic symptoms occur much earlier in the course of arteriosclerotic brain disease than in paresis. Mentally the essential differentiating factor is the long-retained feeling of illness, *i.e.* insight in arteriosclerotic diseases is retained, the slower progression of the loss of mind, the patient retaining his psychic personality until late in the course, in contrast to paresis, where insight is lost early and practically never regained, and loss of intellectual powers and formation of delusions are much more rapid. There is a splitting of the personality early in paresis, while in sclerotic disturbances this occurs very late in the disease. In the majority of cases of sclerotic mental disturbances the general picture has a depressive and anxious

coloring, which is in contrast to the happy, euphoric state of exaltation so very common in paresis. Rarely is the case reversed. In sclerotics who are exalted their ideas are relatively sensible compared with those ridiculous and foolish states in paretics, also even in the excitement stage the sclerotics retain a knowledge of their personality and social position.

To differentiate arteriosclerotic dementia from senile dementia is not always easy. In some cases we have symptoms which resemble both conditions, and the two conditions are commingled. The arteriosclerotic may pass into the senile stage of dementia. Characteristic of the pure senile case is the general loss of memory, almost total loss of memory for recent events while memory for remote events may be practically impaired. In senile dementia absence of focal symptoms is generally the rule. Senile dementia occurs after 70, but may occur earlier in psychopathic individuals.

The retention of psychic personality and relatively long-retained insight and presence of focal symptoms speak for arteriosclerosis.

From manic-depressive attacks the absence of physical arteriosclerosis, history of previous depressions or excitement, and age. It is said that manic-depressive patients are liable to early arteriosclerosis.

Therapeutically, little is to be done beyond what all mental disorders require—provision for safe and simple conditions of life, avoiding of encumbrances in the intestinal tract, and of states which naturally increase blood pressure, such as worry and anxiety. The principal value of our knowledge of the disorder is undoubtedly the prognostic one and that of early recognition of danger in business transactions, naturally, also the avoidance of confusion with syphilitic processes which would demand specific measures.

GASTROALBUMORRHEA IN GASTRIC CANCER.

By MAX KAHN, M.D., PH.D.,

AND

I. JACOBOWITZ, M.D.,

NEW YORK.

(From the Beth Israel Hospital Chemical Laboratory, New York.)

On the assumption that malignant disease of the stomach is accompanied by degeneration processes which liberate débris and protein matter into the stomach cavity, Salomon[1] recommended a test which he thought was diagnostic of cancer of the stomach. This theoretical assumption is in accordance with our knowledge of cancer in general, and the results reported by various observers would seem to bear out the theory. It must be remarked, however, that such diseases as gastric ulcer would also cause a gastroalbumorrhea, as has been demonstrated by several opponents of Salomon's test.

Salomon's method for testing the stomach contents for the albumin fraction is as follows: The stomach is first carefully washed on the evening before testing, after a preliminary non-albuminous fluid diet had been administered for twenty-four hours. On the next morning the stomach is thoroughly washed with normal saline solution (400 c.c.) the same fluid being repeatedly used and then tested for the quantity of nitrogen by the Kjeldahl method and for the quantity of albumin by the Esbach method.

Salomon found the nitrogen content in non-carcinomatous cases to be between 0 and 16 milligrams per 100 c.c. of fluid. His study of six cases of cancer of the stomach revealed between 10 and 70 milligrams of nitrogen per c.c., and the albumin content was between 0.06 and 0.5 parts per thousand. According to Salomon a case is extremely suspicious of carcinoma if the nitrogen content is more than 20 milligrams per 100 c.c. of the fluid, or if the Esbach test gives a distinct precipitate.

Wolff and Junghans[2] modified the Salomon technique somewhat. They determined the albumin by the phosphotungstic acid reagent. They obtained very good results. Smithies[3] found that the Wolff-Junghans modification is of decided value. Another modification of this test has been recommended by Goodman,[4] who desired to eliminate the labor involved in a Kjeldahl determination. He analyzed the gastric contents for phosphorus.

Siegel[5] concurred with Salomon's opinion, concluding from his own results that a figure over 25 milligrams of nitrogen per 100 c.c. is auspicious of gastric cancer, Orlowski,[6] Schittenhelm and Lowes,[7] Zirkelbach,[8] Witte,[9] and Schupfer[10] are convinced that the Salomon test is of value. Gerster regards this test as useful in cancer of the lesser curvature without stenosis, unless the cancer has formed on an old ulcer, in which case the little hydrochloric acid present would digest the albumin present. Zirkelbach, however, is of the opinion that the minimum nitrogen content suggestive of cancer is 30 milligram nitrogen per 100 c.c. of the washing fluid. Berent and Guttmann,[11] Romano, Minkowski and Yague[12] have reported very unfavorable results with this test. Goodman, on the basis of his findings with his modified technique, concluded that: (1) In normal individuals and in persons suffering from diseases exclusive of carcinoma of the stomach, the Salomon test gives more than 20 milligrams of nitrogen per 100 c.c. of wash water; (2) not all cases of gastric carcinoma reveal more than 20 milligrams of nitrogen—the absence of ulcertation is probably responsibile for this; (3) the test is by no means pathognomonic and can be considered as contributary only to the other symptoms; (4) the phosphoric acid of the wash water of a non-carcinomatous case is less than 10 milligrams per 100 c.c., whereas in cancerous conditions it usually exceeds 10 milligrams.

Before discussing the results which we have obtained, mention should be made of the work of Clarke and Rehfuss,[13] which was communicated by Hawk before the Columbia University Biochemical Association. The following is a summary of their findings: "The protein content of the gastric juice was investigated by the method of Wolff, namely, by successively diluting the gastric juice and adding phosphotungstic reagent. It was found that the normal gastric juice *per se* contained only traces of protein, never giving a reaction in dilutions greater than 1:40. The protein content of the specimens removed by the fractional method, after the administration of Ewald meals, was also determined. The macerated Ewald meal *in vitro* never gave a reaction in a dilution greater than 1:40. Treated in

the incubator with artificial gastric juice, the authors were able to demonstrate an increasing content due to the effect of the gastric juice on the proteins of the bread. If, therefore, material removed from the stomach at intervals develops a greater protein content than the theoretical content due to the action of the gastric juice on the bread proteins, we are able to say that it comes from other sources than bread." In cancer the authors found a high protein coefficient.

TABLE I.—ALBUMIN IN THE GASTRIC WASHINGS OF NON-GASTRIC CASES

We have examined the gastric washings of 43 patients—15 gastric carcinoma, 3 esophageal carcinoma, 18 noncancerous diseases of the stomach, and 7 cases in which the patients had no gastric symptoms whatsoever. The washings were analyzed for nitrogen by the Kjeldahl method and for albumin by the Esbach, Tsuchiya, and Pfeiffer methods.[11] In nearly all cases we obtained a higher result with the Tsuchiya method and the highest albumin figure with the Pfeiffer method. In the fifteen cases of gastric cancer the nitrogen content of the washings varied between 27.9 and 71.5 milligrams per 100 c.c. Intermediate figures were obtained in the three cases of esophageal carcinoma. In several cases the diagnosis of malignancy was confirmed by subsequent operation or necropsy. The protein content of the washings in the cases of malignancy was invariably high, never less than 0.4 parts per thousand and occasionally as high as 1.2 parts per thousand by the Esbach method. The smallest figure for protein obtained by the Pfeiffer method was 0.6 parts per thousand and the highest figure was 1.4 parts per thousand. Of the seven cases of gastric ulceration, six gave nitrogen and protein figures, which were similar to the ones obtained in the cases of malignancy. In a case of acute gastritis high nitrogen and protein indices were obtained. In the cases of non-gastric disease the washings were either entirely free from protein or else they contained extremely minute traces.

We did not think the Goodman modification to be of sufficient value to lay any stress on it. The test should be performed in a well-equipped laboratory, and cannot be performed to advantage in the usual laboratory of the practitioner.

In our hands the estimation of the albumorrhea in cases of gastric disease has been of great aid in the differential diagnosis of gastric cancer from a benign condition. Care must be observed to eliminate gastric ulcer and acute inflammation of the stomach mucosa, for as will be seen from our data, these conditions also cause the exudation of protein matter into the stomach cavity.

HOW TO BLOW THE NOSE.

BY E. HARRISON GRIFFIN, M.D.,

NEW YORK.

THE child is taught the alphabet to read. The vocal teacher imparts the use of the voice to a pupil to make him master of the singing art. The mother teaches the child to walk after he has learned to creep. Thus certain members of our anatomy undergo a certain special course of instruction before they render their five talents worth of usefulness to the bulk called the human system.

I have specialized in the nose and throat for over thirty years, and in my hospital experience in the old Bellevue clinic and in my private practice I do not think I have seen twenty-five patients who knew how to blow their noses properly unless they had been previously taught.

The failure to clean the nose by the handkerchief thoroughly is responsible for over 75 per cent. of the catarrh cases that apply for treatment. The in-

correct way of cleansing the passage is also responsible for any number of ear cases.

Years ago when I was a student at school and we were marshalled out in a line preparatory to our march to the Large Room I once blew my nose. A student back of me touched me on the shoulder and said, "Griffin, if you blow your nose that way, you will be deaf when you grow up." That man has been a patient of mine for years. He was so deaf when he first applied for treatment that I could only make him hear by speaking loudly into his ear. His deafness was caused by faulty use of the handkerchief.

The average winter cold starts in the head. The patient instead of properly using his handkerchief begins to hawk the secretion back into the nasopharynx; then some of the mucus is expectorated, while a certain amount will remain glued to the pharynx and the inner border of the soft palate. This will become loosened when the patient moves from one temperature to another, like leaving the house to go out-doors or *vice versa*. Then there is a constant string of mucus hanging down from the palate. This mucus keeps up a constant cough; the cough that is known as a winter cough. This cough is only a symptom of faulty handkerchief service. Cough medicines are given again and again and fail to relieve. The morphine and codeine of cough syrups may benefit, but only benefit by soothing the general system.

The cough syrup passes down the pharynx into the esophagus and then the stomach, but does not strike the point where the irritation lies, namely, the nasopharynx.

The morning vomiting of catarrh is produced by this accumulation on the pharynx and the palate of a large amount of mucus that has been hawked back and has no place to go except to the buccal cavity to be expectorated from the throat.

This constant hawking and cleansing of the nose through the throat is responsible for a constant irritable pharynx and the vomiting to which some persons are so prone.

Elongated uvula is diagnosed again and again in these cases and part or whole of this member is removed. The uvula is not often responsible for a cough. I very seldom see an elongated uvula. During some years I will go the whole twelve months and never see one that demands an operation. Still, this is the field for the general practitioner and one when he operates again and again, and, I think, distinctly without any benefit. The cough or tickling in the throat is not caused by the uvula. The congestion of the uvula is caused by the bunch of phlegm and the habit of hawking on the part of the patient.

If we consider the nose simply as an appendix of the face, the importance of this organ is lost. The nose is the grand central terminal of the air tract. It is here where the various branch lines have their juncture. To see this perfectly an *x*-ray picture of the chest is necessary. If the picture has been taken from a cadaver when the bronchi have been filled with shot, the picture is more than expressive.

The trachea divides low down into the right and left primary bronchi which continue down into the lung tissue to break up into various branches deep into the mammary region. These structures are all used in properly cleansing the nose. When the nose is not properly cleansed all these tissues feel the effect. The nose is the open sesame to these most important organs, the lungs.

I do not think I put it too strong to state that the improper use of the handkerchief is a salient factor in the development of consumption.

The nose can be divided into two parts: the bony part, contained within the skull, and the soft part that extends from the face. The bony part opens into the nasopharynx, the site of the adenoid and the space for the pharyngeal orifice of the eustachian tube.

The bony part of the nose drains the frontal cells, the antrum of Highmore, the lacrymal duct. Thus it can be easily seen that the nose acts not only as an organ of smell, an organ to breathe through, but as a general drain for the sinuses of the skull or head.

All these discharges have to be removed by the handkerchief. A noted specialist once applied to me and explained that his nose was always obstructed and that he could not obtain any air through his nostrils. He illustrated this by breathing in my presence and sucking the alæ nasi together which rendered the nose hermetically sealed. He thought the way to breathe through the nose was to suck the alæ nasi in toward the septum. I quickly saw his mistake and illustrated by my own nose how it would close up if I breathed the way he did. He was much surprised when I told him the way to breathe was from the chest with the chest as a bellows and the nose as the end of the bellows. The nose must be passive. The alæ nasi must be passive in breathing. The alæ nasi, in other words, constitute a cover to the nose and should be used as such.

If we approach a disagreeable smell, the smell ceases to be an objection by sucking the sides of the nose in or holding them together by one finger and thumb. This is the purpose of the fleshy muscular partitions that frame the nose from the face.

Forced inspiration will bring the alæ nasi together. This is seen in the second stage of pneumonia, when the breathing is rapid and panting and the face of dusky hue. Marked movements of the nares are here apparent.

An actor that I had as a patient would take one of my towels that I use in my nose work, touch his nose with the linen and then extend his hand and give the towel a gentle pitch toward his back. He would use up about ten linen towels in this performance and still he never blew his nose. Ladies will take their handkerchiefs, touch their noses gently and put the handkerchief back into the reticule and consider they have emptied their nostrils of a normal secretion.

The baby will hold the secretion in his nostril till it overflows, then it will drain down on his lips and be wiped away by its nurse or parent.

The nose of the adult very seldom overflows toward the front. The drain as I have pointed out before is toward the back, when the flow or current of mucus is augmented by the habit of hawking.

The "Benjamin Backbite" of "The School for Scandal" on the stage is never seen without a large lace handkerchief whose center part is so small that a few tears from the lacrymal duct would make it dripping wet. These kerchiefs of the past show that the art of blowing the nose was as badly understood in former ages as in the present.

The proper way to blow the nose must be a lost art, because at some time in our existence we must have been human and known by instinct how to use our anatomy properly before Dame Fashion came in with the kerchief and lace.

To blow the nose properly it is best to look at it as a double shotgun; the nose as the muzzle of the

gun and the chest as the air receiver, the mucus in the nose as the bullets and charge.

A deep inspiration to fill the chest with air, then one finger is placed upon the ala of one nostril to obstruct the passage. With one violent expiration the air from the chest is forced through the open chamber of the nose and the offending discharge is caught by the handkerchief. This maneuver is repeated on the opposite side. It is a simple mechanical process and one that I have pointed out before, but is seldom known.

We have our tooth-brush drill in the public schools, why not the nose drill? If it was instituted and the pupils taught the proper use of the little piece of linen, catarrh would be diminished, ear cases would be less common, and the germs that first find their way into the anatomy through the nostril would be expelled before they had time to find a sleeping place in the human network.

55 West Forty-seventh Street.

Medicolegal Notes.

Optometrists Not "Practitioners in Medicine" Within Pennsylvania Licensing Statutes. — Injunction was sought in the Pennsylvania courts to restrain members of the State bureau of medical education and licensure of the department of public instruction from enforcing against the plaintiffs, who practised as optometrists the provisions of the Pennsylvania Acts of June 3, 1911, and July 25, 1913. These statutes provide that it shall not be lawful for any person to hold himself or herself forth as a practitioner in medicine unless he or she has first fulfilled the requirements of the acts and received a certificate of licensure.

It appeared from the proofs that the business or profession of optometry is one of ancient standing. Until a comparatively recent date a large part of that which is done by optometrists was exclusively within their province, and was not covered in practice by the physician or surgeon. Within the last quarter of a century, or thereabouts, it appeared from the proofs that among those who are engaged in making lenses to correct or cure defects in the eyes there has arisen a classification, or division, whereby some who make lenses confine themselves entirely to the work of making them in accordance with the prescriptions given them by physicians or oculists. These call themselves, or are known, as "opticians"; others, who still manufacture the lenses, according to either their own judgment or the prescription of physicians, do not confine themselves to the making of lenses, but also examine the eyes for the purpose of ascertaining whether there are such defects visible as can be corrected by the application of lenses. This class have taken the name of "optometrists," and that is the name by which they are now generally known. Those who practise under the latter title are many in number, and they are recognized in many States of the Union as a class by themselves, and regulated by statute.

The court held that an optometrist is not a "practitioner in medicine" within the meaning of the statutes. It did not consider that the fact that the work done by the eye specialist physician and that done by the optometrist, to a certain limited extent, lap over each other, constitutes the optometrist a practitioner in medicine. "Such work on the part of the optometrist was done by him perhaps, and probably, long before the eye specialist among physicians had either the knowledge or the skill to do the work which is now done by both physicians and optometrists. . . . So far as the alleged danger to patients from the application of glasses or lenses upon an examination which did not disclose a hidden disease, a point urged with great force on behalf of the defendants, it seems to us that such a consideration throws no light upon the meaning of the statutes or their bearing upon the case in hand. It might constitute a sufficient reason for the Legislature to regulate the practice of optometry by special enactments, or, by suitable enactments or amendments, to bring optometrists within the regulative control of the defendants making up the board intrusted with the supervision over such matters as are involved in the present case."

It was claimed that the plaintiffs came under the statutes because they diagnosed diseases. The proofs were to the effect that optometrists, examining the eye of a patient, either with or without the aid of artificial means, in case they find that the interior of the eye is clouded and gives ground for suspicion that there is some disease of the eye, inform the patient that, for his own protection and safety he should consult a physician. The court understood that under such circumstances the optometrists decline to furnish lenses for the patients. The court held that this alone was not diagnosis within the meaning of the acts. It thought that a fair and usual construction and interpretation of the words "diagnose diseases," such as ought to be given in determining the meaning of the acts in question, was that the mental act involved in the matter of diagnosis should be something more than the mere determination that there were indications of disease.—Martin v. Baldy, Pennsylvania Supreme Court, 94 Atl. 1091.

Privileged Communications — Arizona Law as to Waiver.—The United States Supreme Court holds that neither the testimony of other witnesses, offered by the patient, nor his own voluntary testimony as to his physical condition at the time of his examination by a physician, nor any averments in the pleadings, amount to a waiver of his privilege, under the provision of the Arizona statute as to privileged communications, against the disclosure by the physician of any communications made by the patient with reference to any physical or supposed physical ailment, or any knowledge obtained by personal examination of the patient. According to the proviso of the Arizona statute, the privilege may be waived only in the event that the patient offers himself as a witness and voluntarily testifies with reference to the "communications" made by him to the physician.—Arizona & New Mexico Ry. Co. vs. Clark, 35 Sup. Ct. Rep. 210.

Care Required in Obstetrical Cases. — The question whether a physician or surgeon, charged with malpractice, has treated the patient or performed an operation with reasonable skill and care, is ordinarily to be tested by the standards of the school to which the physician or surgeon belongs; but if there is uniformity in the rules of practice and treatment, regular practitioners of any school are competent witnesses as to the proper diagnosis and treatment. Where a person who holds himself out as a medical expert or healer has no fixed rules of practice, he is still bound to treat patients with ordinary skill and care, and competent physicians regularly engaged in the practice are competent witnesses as to whether the treatment administered in the case was properly or negligently given. In an action for malpractice, where the defendant was an osteopathic physician, and professed to practise according to the rules and methods of that branch of the profession, it was held that physicians of the regular school were properly permitted to testify as to the progress and condition of labor in an obstetrical case, the methods of delivery and the proper treatment of the mother after the birth of the child.

Ordinarily, only physicians and surgeons of skill and experience are competent to testify as to whether a patient has been treated or an operation performed with a reasonable degree of skill and care, but testimony as to many matters connected with the treatment of a patient, such as the statements and acts of the physician or surgeon, as well as the external appearances and manifest conditions, which are observable by any one, may be given by more expert witnesses.

A physician employed in an obstetrical case is required to care for and aid the patient, not only during her confinement and the delivery of the child, but it is his duty to make a careful examination of the patient and give reasonable and proper attention to any lacerations or injuries resulting from the delivery; and if he fails in this respect or to inform the patient or those caring for her as to her condition, or to give them instructions so that they may act intelligently in the further care and treatment of the patient, he is guilty of negligence and liable for the resulting injuries. An objection that the Kansas statute does not permit an osteopath to administer drugs or medicine or perform operations in surgery, and that therefore he could not legally take any steps to repair a laceration, was met by the opinion that if an osteopath may lawfully attend an obstetrical case such a repair might be regarded as a mere incident of the delivery rather than an operation in surgery.—Yard v. Gibbons, Kansas Supreme Court, 149 Pac. 422.

PELLAGRA.

PELLAGRA is chiefly prevalent in this country in the South and is, moreover, especially frequent in mill districts and closely associated with a condition of poverty. Again observation tends apparently to indicate a considerable increase in the prevalence of pellagra during the past seven or eight years. The suggestion is at once obvious that there is a possible relationship between the incidence of pellagra and certain conditions of an economic nature. In *Public Health Reports*, Oct. 22, 1915, Edgar Sydenstricker, U. S. Public Health Service, contributes various data on this phase of the question.

He summarizes briefly some conclusions afforded by industrial and budgetary investigations regarding (1) The relation of the wageworker's family income to diet, with certain data relating to wages and income of workingmen's families and to the adequacy of wages and family income measured by the cost of living of wage earners in the South as compared with wage earners in other sections of the United States. (2) Some factors affecting the availability of the food supply in Southern industrial localities. (3) Differences in the diet of workingmen's families in Northern and Southern States. (4) Some factors having a possible effect on the diet of Southern wage workers' families in recent years, including the source of the recent labor supply in Southern factories and mills and the urban movement of population, changes in the character of the food supply, changes in the status of Southern wage earners' families, and the recent rise in the retail prices of food. The following conclusions were formulated as a result of this inquiry: (1) The lower the economic status of the white American family, the greater is the pressure for sacrifices in diet, particularly in animal protein foods, since such are the most expensive. (2) The economic status of wage-earners' families in the Southern States, particularly of cotton-mill families, is lower than that of wage-earners' families in other sections of the country. (3) Certain factors have tended to restrict the supply of protein foods in Southern industrial localities that do not restrict, at least to the same extent, the supply of carbohydrates and hydrocarbons. (4) Budgetary studies of a large number of native white earners' families generally comparable as to annual family income and size, indicate that the proportion of proteins in the diet of Southern families is considerably less and of carbohydrates and hydrocarbons considerably greater than in the diet of Northern families. (5) Certain facts have tended to intensify the condition in recent years, particularly since the industrial depression began in the latter part of 1907. While the supply of a properly balanced diet in Southern industrial localities has apparently not been improved materially, the economic status of wage-earners' families, especially in the cotton goods and lumber industries, has been lowered, and retail prices of food have greatly increased, this increase being more pronounced, particularly since 1907, than in other sections of the country. The increase in retail food prices has been at least 40 per cent. higher in proteins than in carbohydrates and hydrocarbons. The available data thus point to a lessened financial ability of Southern wage-earners' families to provide a properly balanced diet, as well as a decrease in the availability of an animal protein food supply for the wage-working population, particularly since 1907 or 1908.

The same issue of Public Health Reports contains papers by Drs. Joseph Goldberger, C. H. Waring, and David G. Willets, U. S. Public Health Service, with regard to tests of diet in institutions. The summary and conclusion are as follows: (1) The diet at two orphanages, "M. J." and "B. J.," for several years endemic foci of pellagra, was modified in accordance with the direction of the writers in September, 1914. The hygienic and sanitary conditions have remained unchanged. (2) The modification in the diet consisted principally of a marked increase in the fresh animal and the leguminous protein foods. (3) Since the change of diet at orphanage "M. J." there has not been observed any recognizable evidence of a recurrence in any of the pellagrins of 1914, 67 of whom remained under observation until they had completed at least the anniversary date of their attack. Nor have any new cases been observed among the non-pellagrin residents of 1914, 99 of whom have been under observation for not less than a year. (4) Since the change in orphanage "B. J." there has been observed this year but a single individual with recognizable evidence of a recurrence among the pellagrins of 1914, 105 of whom remained under observation until they had completed at least the anniversary date of their attacks. Nor has any new case been observed among the non-pellagrin residents, 69 of whom have been under observation not less than a year. (5) At the Georgia State Sanatorium, an endemic focus of pellagra, a ward of pellagrins in the colored female service and one in the white female service were organized in October and December, 1914, respectively, for a test of diet in the prevention of pellagra. (6) The diet in these wards was modified on the same principle as that at the orphanages. The institution routine and the hygienic and sanitary conditions have remained unchanged. (7) Since the change of diet and up to Oct. 1, 1915, there has not been observed any recognizable evidence of a recurrence in any of the pellagrins in these wards, 72 of whom have remained continuously under observation throughout the period or at least until the com-

pletion of the anniversary date of their 1914 attacks. (8) During the corresponding period of observation not less than 15 (47 per cent.) of 32 control female pellagrins have presented recurrences. (9) The conclusion is drawn that pellagra may be prevented by an appropriate diet without any alteration in the environment, hygienic or sanitary.

From the foregoing data drawn from careful observations, it would seem that pellagra, after all, is a "mal de misère" that is brought about by an inadequate and unsuitable diet. Always the disease appears to go hand in hand with extreme poverty and does not occur when individuals are fed well and on a sufficiency of animal protein food. The results of the investigations made by Dr. Goldberger and his co-workers, although they by no means clear up the mystery of the cause of pellagra, yet do further substantiate the views held by so many that pellagra is mainly a dietetic disease, a malady induced by errors of diet irrespective of the influence exerted by bad sanitation or hygiene.

LESIONS PRODUCED BY ARSENICALS.

THERE is no other group of drugs to which so much attention has been accorded within recent years as the compounds of arsenic. They have occupied the center of interest in chemotherapy ever since Laveran and Mesnil in 1902 demonstrated the trypanocidal action of arsenic in laboratory animals. Then came the striking achievements with the use of atoxyl in spirochetal infections which began the series of investigations that culminated in Ehrlich's contribution to what was at first thought to be the specific therapy of syphilis. From the very inception of the use of arsenic as a therapeutic agent, even in the older days when its parasiticidal action was not even suspected, the adverse effect of this chemical agent upon the body cells was definitely recognized. These effects have been greatly accentuated in the case of the heroic applications of this drug in the various spirochetal infections. The problem in the modern chemotherapy of arsenic has been to evolve compounds of this drug that would produce the greatest therapeutic effect and at the same time exert the least toxic influence upon the cells and tissues of the individual under treatment.

The knowledge of these toxic effects has been extremely vague although the pathology of arsenic poisoning has been known for a long time. Wade H. Brown and his associates have studied this subject for several years and the results are reported by Brown in an important paper in the *Bulletin* of the Johns Hopkins Hospital, September, 1915. About sixty different compounds of arsenic were studied as to their effects upon the important organs of the body. The already well-known lesions of arsenic poisoning are not alluded to. An important group of changes are those found in the heart and blood-vessels. Some arsenic compounds, such as atoxyl in relatively large doses and salvarsan and its modifications, produce subendocardial and myocardial hemorrhages and hemorrhage into the substance of the heart valves. Vascular occlusion resulting from thrombus formation or the presence of emboli is another important effect of arsenic poisoning. Characteristic lesions in the lungs consist of petechial hemorrhages finely and uniformly distributed throughout the lung. The hepatic lesions are divided into three groups: (1) diffuse degenerative changes similar to those produced by inorganic compounds of arsenic; (2) lesions of the central zone of the liver lobule including degenerative processes and necroses; and, in the case of one compound of arsenic, characterized chiefly by profuse hemorrhage into the bile-ducts; and (3) lesions produced by preferential action upon portal structures and the peripheral zone of the lobule. One important characteristic of the toxic action of arsenic is the fact that the most pronounced effect is produced by the first injection. Apparently the regenerated tissue of the injured territory acquires a distinct degree of tolerance or tissue fastness. In some instances, however, there is produced a condition of tissue sensitization in which the effect of a later dose may be more marked than those of an earlier dose.

Brown differentiates two types of kidney lesions produced by inorganic compounds of arsenic; (2) In one of these, known as the red kidney, the necrotic lesions involve all the elements of the kidney, or may exhibit a preferential action as regards the vascular, cortical, or medullary changes. The second type, in which the kidney is extremely pale, exhibits a pronounced involvement of the tubular epithelium. The suprarenal capsules are also affected by the toxic action of arsenic, the type and degree of injury varying decidedly with the different compounds of arsenic and the different animal species, but being parallel with the susceptibility of a given animal species for a given compound.

An important distinction is drawn between toxicity and tissue injury, for one may be diminished without a necessary reduction in the other. The lesion complex is measurably related to the chemical constitution of the compound. The problem for the future is how to evolve compounds of arsenic that will produce the maximum therapeutic effect and the minimum toxic effect. The solution of this problem, the possibility of which is still extremely remote, will require the close co-operation between the clinician and the laboratory investigator.

GARLIC JUICE IN WOUND TREATMENT.

SINCE the great European war commenced many and various modes of treating wounds have been tested and more have been discussed. At the beginning of the campaigns the antiseptic treatment of wounds and injuries in civil life had fallen into disfavor—almost into disrepute—and some authorities had openly stated that the antiseptic method was practically dead. However, after the war had progressed somewhat, it was found that not only were antiseptic principles not dead but that under the conditions which prevailed in the most modern warfare the carrying out of aseptic methods were, generally speaking, impossible and that recourse must be had to Lister's principles. Many measures have been suggested and tried, and among these not

the least successful has been the employment of hydrogen peroxide. Another substance which seems to have proved its worth is garlic juice. In the *Medical Press and Circular*, November 17, 1915, Dr. A. D. Serrell Cooke writes concerning this method. The way in which the juice was used is stated to be as follows: After efficient drainage had been established the infected wound was washed out carefully twice daily with a lotion of garlic juice and distilled water, in a strength of 1 to 3 or 1 to 4. After this treatment in a large number of cases a noticeable improvement occurred in 24 hours and a decided improvement within 48 hours. During this period the purulent discharge not only became markedly diminished, but also the pain and surrounding inflammation were either very much relieved or disappeared. The kind of wounds treated were recent dirty wounds, in which suppuration had not yet occurred; foul, lacerated suppurating wounds of the face, scalp, thigh, etc.; extensive superficial burns of the face, scalp, chest, limbs, and abdomen in children; suppurating bursæ about the knee; cases of empyema; foul ulcers of the leg; infected and suppurating wounds in connection with compound fractures; carbuncle; one particularly interesting case of moist spreading gangrene of the leg in an old woman of 71 years, etc.

The good effects of garlic juice have been ascribed to the active principles contained in the essential oil derived from it; and oleum allii is stated to contain allyl sulphide, in addition to certain volatile terebenes. As the red-skinned varieties of *Allium sativum* are said to contain more of the essential oil than the white-skinned, the juice derived from the former has been chiefly employed.

As a matter of fact, although stress has been laid upon the regeneration, so to speak, of antiseptic principles in the treatment of wounds, the antiseptic value of garlic juice according to the Rideal-Walker tests is but small. Cooke is of the opinion that as the result of the work carried out in Paddington Infirmary with garlic juice, it would seem that in this substance we have at hand a powerful remedy for the treatment of infected wounds. It would appear to possess properties which are cleansing, sedative, deodorant, penetrative, lymphagogic, and possibly also antiseptic. To its action as a lymphagogue probably most of its good results are due, and the results in wound treatment so far achieved by it would appear to confirm in practice, without injury to the tissues, the recently expressed theory of Sir Almroth Wright as to the value of drainage combined with lymph lavage in wound treatment.

WHAT IS DEBILITY?

Is there such a thing as debility? Of course, we all know that the quality the expression intends to represent permeates large areas of mundane things; it extends its baleful influence to political movements, to therapeutic fads, and to good resolutions. But whether there is a clinical entity sufficiently delimited to be known by that name is open to serious doubt.

In the medical dictionaries the term is given as synonymous with asthenia, which is defined as a general loss or absence of strength, adynamia. This latter is in turn defined as a deficiency or loss of vital or muscular power. A lay dictionary defines it as the state or quality of being weak, weakness, feebleness, languor. The international list of causes of death, published by the Census Bureau for the use of physicians, does not mention it at all except under "Ill-defined diseases," where it says, "Some of the old chronics which well-informed physicians are coming less and less to use, are the following: . . . Debility. . . ." We do not find the condition described in Osler, Hare, Sahli, or other well-known works on internal medicine and physical diagnosis.

We must then conclude that debility is itself not a disease, but a symptom, and look behind it for the cause. There are cases, of course, in which it is impossible to determine readily the cause of the debility and where it is necessary to make some diagnosis at once, as for instance, when we have patients in a sick benefit society and it is our task to fill out weekly reports that they may obtain the payments to which they are entitled. In such cases it might be quite proper to certify for the first week or two at least that the patient is suffering from debility, but such a diagnosis can be reconciled to the scientific side of our minds only by the agreement with ourselves that we mean thereby merely that the patient is incapacitated for work because of a general weakness the cause of which we have not yet determined.

Medicine, after all, is not an exact science and attempts to treat it as such are not only futile, but actually detrimental. How many fevers, for instance, do we encounter in our daily practice which last a short while and then disappear and we never know their source or nature? True, we have strong suspicions, but if we were obliged to catalogue them rigidly as influenza, malaria, or autointoxication, would not the future efforts of the profession to master these conditions be impeded by the inclusion of material, much of which in reality belonged elsewhere? Let us, therefore, refer to the patient's condition as debility if that is as far as we have progressed in the diagnosis, and not befog the issue by any pseudoscientific guesses.

Internal Secretions and Gynecology.

In the present state of our knowledge of this subject the internal secretion of the ovary is bound up chiefly in the activities of the corpus luteum. The latter supplies a principle which presides over the growth of the genitals and precipitates menstruation. A second hormone has a hemostatic action on the menses. The two, acting in alternation, cause the entire phenomenon of menstruation. The stroma of the ovary also produces a hormone which protects the development of secondary sexual characteristics. The ovarian secretions antagonize the production of breast milk and may be used in therapeutics to check galactorrhea. There are many facts of gestation which point to the existence of a placental hormone. The ovary and thyroid promote each other's activity. The latter enlarges at puberty and during menstruation and pregnancy. Gestation aggravates ordinary goiter and Graves' disease. In hypofunction of the thyroid the geni-

tals may suffer in development and activity. The hormone of the parathyroids has an activity quite similar to that of ergotin. The above summary was given by Franz Cohn last June at a meeting of the Frankfort Medical Society (*Berliner klinische Wochenschrift,* August 2). Somewhat less obvious are the relations between the hypophysis and female genitals. Hypopituitarism inhibits the development of the latter, but so does the opposite condition of hyperpituitarism. Conversely castration of women is sometimes followed by acromegaly. The phenomena of overgrowth seen during gestation are doubtless due to activity of the hypophysis. Destruction of the epiphysis has caused precocious sexual development. The relations of the thymus with the ovary appear paradoxical. The adrenals are activated by pregnancy and are responsible for its chloasma and various other phenomena. Puerperal osteomalacia appears to be due to a general disturbance of the internal secretions.

Isolated Neuritis Vestibularis Following Typhoid Immunisation.

Since inoculations with dead cultures of germs introduce definite quantities of toxins into the economy, we must expect to see develop in rare instances some mild and brief type of toxigenic lesion. As the nerves are susceptible to toxic inflammations, as shown by the occurrence of alcoholic, plumbic, and luetic neuritis, we would look forward to beholding sooner or later some type of typhoid neuritis in the predisposed. Should a nerve like the vestibularis be the victim the resulting symptoms might be distressing and further be superadded to the systemic action which sometimes develops. Indeed it is by no means improbable that these so-called general symptoms may be largely attributable to inflammation of the vestibular nerve (vomiting, nausea, headache, vertigo). In an article in the *Deutsche medizinische Wochenschrift,* Aug. 19, Hirsch gives the results of a typhoid immunisation in a medical colleague. The latter, a very healthy subject, had borne the first injection without much reaction. The second, however, made twenty-six hours later, caused symptoms which pointed to a neuritis vestibularis. This result suggests that in typhoid fever the same nerve is exposed to injury. As a matter of fact a serous labyrinthitis does occur at times in this affection and causes deafness. But since other portions of the auditory apparatus are prone to implication, isolated neuritis vestibularis is seldom seen.

Bence Jones Albuminuria and Lymphatic Leucemia.

In 1898 Askanazy published case reports of lymphatic leucemia in which Bence Jones bodies were found in abundance in the urine and also in the bone marrow; these, however, were absent in the lymphoid tumors, blood, and exudates. Ten years later von Decastello, with somewhat different finds, arrived at the conclusion that the source of these proteins is the bone marrow, from which they gradually disappear as the disease nears a fatal ending. At a recent session of the Verein für Wissenschaftliche Heilkunde of Königsberg (*Deutsche medizinische Wochenschrift,* September 2) Frohmann reported the case of an adult male with lymphatic leucemia. The general condition was still good and the patient presented only the multiple lymphnode tumors and blood picture, with an abundance of Bence Jones bodies in the urine. Although there were no other evidences of bone marrow implication this find was looked upon as making the diagnosis, which is not, however, specific for myelogenous leucemia, since under different circumstances it could indicate a metastatic carcinosis of the bones. In leucemia it cannot distinguish between primary and secondary forms of bone marrow implication. The *x*-rays have no influence over the production of these bodies, while benzol has been known to reduce and even inhibit their excretion in the urine.

News of the Week.

Disease Among Food-Handlers.—Health Commissioner Emerson recently issued a report of an investigation into the health of persons handling food in the restaurants and cafés of New York. So far about 75 per cent. of the 100,000 hotel and restaurant employees in the city have been examined, and only 3½ per cent. have shown evidence of infectious disease. In only one-half of these was the disease present in a communicable form. The Sanitary Code requires the discharge of all culinary helpers in hotels and restaurants who are considered by the inspectors to endanger the health of the patrons.

Proposed Broad Street Hospital.—The funds so far collected for the proposed new Broad Street Hospital in New York, an institution for the immediate medical and surgical relief of persons injured or taken ill in the big office buildings in the Wall Street District, amount to $50,000, the sum set by some of the wealthy men in Wall Street as the amount to be reached before they would contribute. The prospects for the speedy erection of the hospital are, therefore, good.

Rockefeller Hospital.—The Hospital of the Rockefeller Institute for Medical Research, New York, which receives only selected cases having a bearing on the subjects under investigation, is now admitting patients suffering from acute lobar pneumonia, from broken compensation, especially with edema, and from nephritis. Patients suffering from diabetes mellitus are also being treated, but at present no additional ones can be admitted. Physicians having patients who desire to enter the hospital and are suitable for treatment should communicate with the Resident Physician, either personally or by telephone (Plaza 6800).

Radium Hospital.—The New York Radium Sanatorium on West Seventieth Street, New York, was formally opened to the public on December 1. The sanitarium has at present accommodations for about eighteen persons and can care also for a large number of dispensary patients. About 300 milligrams of radium are already in the possession of the institution, and a considerable quantity in addition has been contracted for. The surgical staff consists of Dr. Cornelius G. Coakley, Dr. John A. Fordyce, Dr. Charles H. May, Dr. George D. Stewart, Dr. Winfield S. Ayres, Dr. Henry C. Coe, Dr. Anthony Bassler, Dr. Eugene C. Savidge, Dr. William C. Lusk, and Dr. Joseph B. Bissell, who is to be the director. The pathologist is Dr. Charles Norris; the dermatologist, Dr. Howard Fox. The director of the medical staff is Dr. Samuel A. Brown; the names of the other members of the medical staff have not yet been announced.

Home for Incurables.—The cornerstone of the

home of the House of the Holy Comforters, New York, a free home for incurables, was laid on December 3. The new building is at the corner of 196th Street and the Grand Concourse, a site which was selected when it was found that the home was outgrowing its present quarters at Riverside Drive and 139th Street. This is the second time that the home has had to move because of rapid increase in the number of applicants.

Personals.—Dr. DAVID BOVAIRD has resumed practice in New York after an extended tour of Siam, the Philippines, China, Korea, and Japan.

Dr. E. V. MORROW of Portland, Me., has been made director and chief surgeon of the Belgian units of the American Red Cross. He will have charge of all the Red Cross relief work in Belgium.

Dr. W. T. GRAHAM, superintendent of the Iowa Methodist Hospital, Des Moines, has been appointed superintendent of the University Hospital, Iowa City, Iowa.

Dr. HENRY H. DOAN has been made Chief of the Division of Child Hygiene of the Bureau of Health of Philadelphia.

Drs. WILLIAM MITTENDORF, SR., and ALFRED D. MITTENDORF have removed to 399 Park Avenue, corner Fifty-fourth Street.

Dr. OTTO T. FREER of Chicago was the guest of honor at a dinner given by Dr. Wolff Freudenthal at his residence in this city on Monday, December 6. At the invitation of the German Medical Society, Dr. Freer made an address on "Opening the Frontal Sinus through the Nose."

Police Census.—The population of New York City, according to the Police Census taken this year, is 5,253,885, which shows a gain of 244,773 over the figure recently given by the State. The population by boroughs is as follows: Manhattan, 2,295,761; Brooklyn, 1,825,534; Bronx, 37,233; Queens, 389,233; Richmond, 93,631.

New Jersey State Census.—The State Census of New Jersey, recently made public, shows that there are now in the State 2,844,342 persons, an increase of 700,208 over 1905, when the last census was taken. There are 734,052 persons of foreign birth, 95,281 negroes; 1,428,189 males; 1,416,183 females; and 1,167,340 married persons. The Irish in the State have decreased from 136,061 in 1905 to 75,444 this year; and the Germans from 119,051 in 1905 to 115,711; while the English have increased from 47,404 in 1905 to 55,357, and the Italians from 75,786 to 144,848.

Losses on Hospital Ship.—The complete statement of the casualties attending the sinking of the British Hospital ship *Anglia* in the English Channel on November 17, shows that four officers, one nurse, and 129 wounded soldiers were lost.

Schechter Memorial.—As a permanent memorial to the work of Dr. Solomon Schechter, the noted Hebrew scholar and head of the Jewish Theological Seminary, New York, who died on November 20, the Federation of Roumanian Jews will dedicate its new Jewish Home for Convalescents at Grandview, Rockland County, N. Y., on April 1. The home will be known as the Prof. Solomon Schechter Memorial. The home was established several months ago at a cost of $200,000, and will accommodate 200 patients.

Street Accidents.—During the month of November, 40 persons were killed by vehicles on the streets of Greater New York, says the report of the National Highways Protective Society. Of these, 29, of whom 14 were children, were killed by motor cars, 5 children and 1 adult by trolleys, and 4 children and 1 adult by wagons. The Police Commissioner recently had tabulated the reports of street accidents in New York from January 1 to November 30, of this year, the total being 567 killed and 20,003 persons injured by vehicles. Of the 567 fatal accidents, 160 were due to automobiles, 89 to motor trucks, 67 to street cars, 88 to horse drawn vehicles, 46 to falls from vehicles, 36 to collisions, and 81 to miscellaneous causes.

Railroad Accidents in Pennsylvania.—Of the millions who rode on passenger trains in the State of Pennsylvania during the year 1914-15 covered by the last report of the Bureau of Accidents, only 2 were killed. During the same period there occurred 11,639 accidents on steam and street railways, resulting in injury to 11,802 persons and in the death of 1,162. Of 999 persons who were killed on steam railways, 609 were trespassers, and 105 were struck at grade crossings. On the street railways 13 passengers were killed, of whom 10 lost their lives by jumping from moving cars.

American Society for the Study of Alcohol and Other Narcotics.—The 45th annual meeting of this society will be held at the Hotel Raleigh, Washington, D. C., on December 15 and 16, 1915. Programmes may be obtained by addressing the secretary, Dr. T. D. Crothers, Hartford, Conn.

New York Geriatric Society.—The first meeting of this society will be held on Wednesday, December 15, 1915, 8.30 P.M., at Sherman Square Hotel, Broadway and 71st street, New York. Subject for discussion: "The Neglect of the Aged." Speakers: Drs. Hermann M. Biggs, Edward T. Devine, Eugene L. Fisk, Thos. E. Satterthwaite, L. F. Bishop.

Medical Society Elections.—NEW YORK ACADEMY OF MEDICINE. At the annual election, held on Thursday of last week, the following officers were elected: *Vice-President*, George David Stewart; *Recording Secretary*, Frederick Theodore Van Buren, Jr.; *Trustee for Five Years*, Nathan E. Brill; *Trustee for Two Years*, L. Emmett Holt; *Committee on Admission*, Walter Lindsay Niles; *Committee on Library*, Arthur B. Duel.

SECOND DISTRICT BRANCH OF THE MEDICAL SOCIETY OF THE STATE OF NEW YORK. Through a change in the by-laws of this society the office of second vice-president was recently created, and Dr. Frederick C. Holden, Brooklyn, was elected to fill it. The officers of the society for the ensuing year are: *President*, Dr. James S. Cooley, Mineola; *1st Vice-President*, Dr. A. H. Terry, Patchogue; *2d Vice-President*, Dr. Holden; *Secretary-Treasurer*, Dr. Charles Eastmond, Brooklyn.

Mental Clinics in Brooklyn.—The Department of Health of New York calls attention to the fact that there are conducted in Brooklyn two clinics where persons suffering from mental diseases may receive free advice and treatment. Both of the clinics are under the direction of the superintendent of the Long Island State Hospital; one is located in the out-patient department of the Polhemus Memorial Clinic of the Long Island College Hospital, and the other is in the Long Island State Hospital. The first is held every Friday afternoon at 2 o'clock, and the second on Saturdays from 10 a. m. to 3 p. m.

Home for Nurses.—Shevlin Hall, the new home for the nurses of Saint Mary's Hospital, Brooklyn, was dedicated by Bishop McDonnell on November 28. The building was erected at a cost of $50,000 as a memorial to the late Mrs. James Shevlin. Accommodations are provided for seventy nurses.

County Tuberculosis Hospital.—The Board of

Supervisors of Jefferson County, New York, has appropriated the $25,000 voted by the people of the county on November 2 for the establishment of a tuberculosis hospital. This sum is in addition to one of $15,000 previously appropriated by the Board. The site for the hospital has been selected and construction will begin shortly.

Navy Medical Corps.—The next examination for appointment in the Medical Corps of the Navy will be held at the various naval stations on or about February 23, 1916. Applicants for appointment must be citizens of the United States and must present satisfactory evidence of preliminary education and medical education. The first stage of the examination is for appointment as assistant surgeon in the Medical Reserve Corps; the successful candidate then attends the course of instruction at the Naval Medical School, beginning about October 1, 1916, and during his attendance receives a salary of $2,000 per annum. On the successful completion of the course he is commissioned an assistant surgeon in the Navy. Full information with regard to physical and mental examinations may be obtained by addressing the Surgeon General of the Navy, Navy Department, Washington, D. C.

New York State Medical Library.—Four years ago the New York State Library at Albany was wiped out by fire, including the medical portion. So quickly was the work of restoration undertaken, however, that to-day the Medical Section contains 19,600 bound volumes, several hundred more than it contained in 1911, several thousand pamphlets and reprints, and much unbound material. About 500 current periodicals are now received, and more than 200 of these are complete from the beginning. The library is prepared to loan these books to licensed physicians, full-time instructors or the faculty of any medical college, members of the house staff of any hospital, registered and certified nurses, and those engaged in pathological research, who offer suitable references. The books are sent by mail and the only expense to the borrower is the payment of return postage. Physicians coming from a distance to consult the library may have books, etc., reserved for them by notifying the librarian in advance. All requests should be addressed to the Medical Librarian, State Library, Education Building, Albany, N. Y. The library solicits gifts of books, periodicals and reprints, and points out particularly that even single volumes or odd numbers of periodicals of little worth to the owner may be of value in completing valuable sets.

School Certificates.—The Bulletin of the Department of Health calls attention to the fact that children and teachers in the public schools who have been out of school because of illness from or exposure to diphtheria or scarlet fever, will be readmitted to the schools only on permits issued by the Department. In cases of measles a certificate from a private physician is sufficient to obtain readmittance.

City Death Rate.—During the week ending November 27, the number of deaths in New York City was 1,318, giving a death rate of 11.84 per thousand of population; while for the corresponding week of last year the deaths numbered 1,389, giving a death rate of 12.98. There was thus an absolute decrease of 71 deaths. The week was one of the healthiest in the history of the city, according to the Department of Health, especially as regards the infectious diseases. Only one death was reported from scarlet fever, three from measles, and eighteen from diphtheria and croup, these figures being much lower than those of any corresponding week. There were 67 deaths from bronchopneumonia, as compared with 94 during the same week of 1914. The death rate for the first forty-eight weeks of 1915 was 13.54 per thousand, as against a rate of 13.71 for the same period of 1914.

Deaths in Chicago.—During the week ending November 27, there were reported in Chicago a total of 601 deaths, which was 55 more than for the previous week of this year, and 57 less than during the same week of 1914, the respective rates per thousand being 12.8, 11.6, and 14.3. Tuberculosis caused 80 deaths, pneumonia, 66, infantile diarrhea, 43, and diphtheria, 16.

Obituary Notes.—Dr. JONAS MULLER of Brooklyn, a graduate of the University and Bellevue Hospital Medical College, New York, in 1913, and physician to the Bedford Hospital and Dispensary, died at his home on December 2, aged 25 years.

Dr. PERRY JAFFA of Trinidad, Col., a graduate of the Gross Medical College, Denver, in 1900, a member of the American Medical Association, and the Colorado State and Las Animas County Medical Societies, and County Physician of Las Animas, died at Denver, after a short illness, on November 2, aged 45 years.

Dr. CLAYTON RANSOM of Mill City, a graduate of the Willamette University Medical Department, Salem, Ore., in 1903, and a member of the American Medical Association, the Oregon State Medical Association, and the Polk-Yamhill-Marion Counties Medical Society, was accidentally shot and killed while hunting near Wilson, Wyo., on September 17.

Dr. GEORGE RICHARD KUHN of Brooklyn, N. Y., a graduate of the Long Island College Hospital, Brooklyn, in 1872, a member of the New York State and Kings County Medical Societies and the Brooklyn Pathological Society, and visiting physician to St. Mary's Hospital, Brooklyn, died at his home, from paralysis, on November 5, aged 68 years.

Dr. MAJOR ALBERT VEEDER of Lyons, N. Y., a graduate of the University of Buffalo Medical Department, Buffalo, N. Y., in 1883, and a member of the New York State and Wayne County Medical Societies, of which latter he was secretary, and the Rochester Academy of Medicine, died at his home on November 16, aged 67 years.

Dr. FRANCIS L. GALT, surgeon on the Confederate cruiser Alabama during the Civil War, and a member of the party which first explored the head waters of the Amazon, and a graduate of the University of Pennsylvania, Department of Medicine, Philadelphia, in 1854, died at his home in Upperville, Va., November 17, aged 83 years.

Dr. NEHEMIAH DAVIS of Camden, N. J., a graduate of the Philadelphia College of Pharmacy in 1878, and of the Jefferson Medical College, Philadelphia, 1886, died at his home on November 11, aged 60 years.

Dr. KATHERINE KOLLOCK of Philadelphia, a graduate of the Woman's Medical College of Pennsylvania, Philadelphia, in 1887, and a member of the American Medical Association, the Medical Society of the State of Pennsylvania, and the Philadelphia County Medical Society, died at her home on November 17, aged 70 years.

Dr. JOHN HENRY DE WITT of Philadelphia, Pa., a graduate of the Jefferson Medical College, Philadelphia, in 1880, died at his home on November 15, aged 60 years.

Dr. AUGUSTUS W. DUVALL of Philadelphia, a

graduate of the Jefferson Medical College, Philadelphia, in 1877, died at his home from uremia, on November 11.

Dr. JOHN A. REESE of Philadelphia, a graduate of the Medico-Chirurgical College of Philadelphia in 1883, died on November 11, as the result of injuries received when he was struck by a motor car a few days before.

Dr. ROBERT DAVIS WEBB of Philadelphia, a graduate of the Medico-Chirurgical College of Philadelphia in 1893, died at his home on November 13, aged 44 years.

Dr. GEORGE M. BURDETTE of Lenoir City, Tenn., a graduate of the University of Georgia, College of Medicine, Augusta, in 1896, a veteran of the Civil War, having served throughout in the Confederate army, and a member of the American Medical Association, the Tennessee State Medical Association, and the London County Medical Society, died at his home from apoplexy, on November 5, aged 78 years.

Dr. WILLIAM MCKAY of Reserve Mines, N. S., a graduate of the Bellevue Hospital Medical College, New York, in 1873, and a member of the Canadian Senate since 1913, died at his home, after a short illness, on November 9, aged 68 years.

Dr. VALENTINE BROWNE of Yonkers, N. Y., a graduate of the New York University Medical College, New York, in 1875, formerly health officer and school trustee of Yonkers, consulting physician to St. Joseph's Hospital, and a member of the American Medical Association, and the New York State and Westchester County Medical Societies, died at his home, from angina pectoris, after a short illness, on November 19, aged 83 years.

Dr. CHARLES GRANVILLE STONE of Washington, D. C., a graduate of the University of Maryland, School of Medicine, Baltimore, in 1872, and a member of the American Medical Association and the Medical Society of the District of Columbia, died at his home, after a long illness, on November 11, aged 69 years.

Dr. JOHN F. RICHARDS of San Francisco, Cal., a graduate of the College of Physicians and Surgeons, San Francisco, in 1907, was accidentally shot while quail shooting on November 7, and died shortly after, aged 40 years.

Dr. GREGORY PAUL of New York, a graduate of the New York University Medical College in 1888, and formerly professor of medicine in the University of Aintah, Turkey, died in the Post-Graduate Hospital, New York, on November 23, aged 57 years.

Dr. JOHN P. DUNNIGAN of Washington, D. C., a graduate of the Georgetown University School of Medicine, Washington, in 1901, obstetrician to the Providence Hospital, and a member of the Medical Society of the District of Columbia, died in the Providence Hospital, after a long illness, on November 11, aged 41 years.

Dr. WILLIAM VIRGIL NEWSOM of Ocala, Fla., a graduate of the College of Physicians and Surgeons, Baltimore, in 1887, a member of the American Medical Association, the Florida Medical Association, and the Marion County Medical Society, and a former president of the last, died at his home after a long illness, on November 11, aged 57 years.

Dr. HORACE B. HEYSHAM of Norristown, Pa., a graduate of the Jefferson Medical College, Philadelphia in 1900, and formerly resident physician in the Charity Hospital Norristown died at his home on November 15 aged 42 years.

Dr. EDWIN FORREST PHILIPS of Tower City, Pa., a graduate of the Jefferson Medical College, Philadelphia in 1871, died at his home from pneumonia, on November 17, aged 67 years.

Dr. ROBERT H. MITCHELL of Memphis, Tenn., a graduate of the University of Pennsylvania, Department of Medicine, Philadelphia, in 1897, and a member of the American Medical Association, the Tennessee State Medical Association, and the Shelby County Medical Society, died at his home after a brief illness, on November 14, aged 41 years.

Dr. GEORGE EDWIN PINKHAM of Lowell, Mass., a graduate of the Dartmouth Medical School, Hanover, N. H., in 1863, a veteran of the Civil War, city physician of Lowell from 1866 to 1868, and a member of the Massachusetts Medical Society and the Middlesex North District Medical Society, of which he was president for two years, died at his home after a long illness, on November 15, aged 75 years.

Dr. GEORGE REULING of Baltimore, Md., a graduate of the University of Giessen, Germany, in 1866, emeritus professor of diseases of the eye and ear in the Baltimore Medical College, formerly surgeon-in-chief of the Maryland Eye and Ear Infirmary, and a member of the American Laryngological, Otological, and Rhinological Society, died at his home on November 25, aged 76 years.

Dr. JOHN PATRICK STANTON of Scranton, Pa., a graduate of the University and Bellevue Hospital Medical College, New York, in 1899, was instantly killed in an automobile accident on November 25.

Dr. JOHN HOCKENHULL of Cumming, Ga., a graduate of the University of Georgia, College of Medicine, Augusta, in 1855, died at his home on November 13, aged 83 years.

Dr. NATHANIEL RITTER died at Allentown, Pa., on November 21 as the result of an automobile accident at the age of 76 years. He was graduated from Jefferson Medical College in the class of 1861.

Dr. JOHN C. HUTTON died at Harrisburg, Pa., on November 21 at the age of 70 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1867.

Dr. FREDERIC W. MESSERVE died at Berlin, N. J., on November 22 at the age of 55 years. He was graduated from Hahnemann Medical College and Hospital of Philadelphia in the class of 1885. He was at one time resident physician in Hahnemann Hospital, and later professor of ophthalmology in Hahnemann Medical College, and ophthalmologist to the New Jersey Homeopathic Hospital in Camden and to the Children's Homeopathic Hospital in Philadelphia.

Dr. HENRY HARRISON RIEGEL died at Catasaqua, Pa., on November 25, at the age of 79 years. He was graduated from Jefferson Medical College in the class of 1857. He was at one time Pension Examiner, School Director, Burgess, and President of the Lehigh County Medical Society, as well as a member of the Medical Society of the State of Pennsylvania and a Fellow of the American Medical Association.

Dr. JOHN C. WEBSTER of Chicago, a graduate of the Harvard University Medical School, Boston, in 1867, and a member of the Illinois State Medical Society, and the Cook County Medical Society, died at his home on November 15, aged 72 years.

Dr. GEORGE HENRY WILKINS of Newtonville, Mass., a graduate of the New York Homeopathic Medical College and Hospital, New York, in 1883, died in the Woodside Cottage Sanitarium, Framingham, Mass., after a long illness, on November 17, aged 59 years.

Dr. FREDERICK WILLIAM RUSSELL, formerly of

Winchenden, Mass., a graduate of the New York University Medical College in 1871, a hospital steward during the Civil War, a former member of the Massachusetts and Worcester District Medical Societies, and an honorary member of the Dallas Medical and Surgical Association, died at the home of his son-in-law in Dallas, Texas, after a long illness, on November 20, aged 71 years.

Dr. FRANK JOSEPH SYKORA of Brainerd, Minn., a graduate of the Chicago College of Medicine and Surgery in 1909, and a member of the American Medical Association, the Minnesota State Medical Association, and the Upper Mississippi Medical Society, died in St. Joseph's Hospital, St. Paul, after a long illness, on November 17, aged 38 years.

Dr. WILLIAM HENRY MORSE of New York, a graduate of the Bellevue Hospital Medical College, New York, in 1871, and a member of the Greater New York Medical Association, died at his home from cerebral hemorrhage, on November 26, aged 65 years.

Dr. GEORGE WASHINGTON WELTY of Brooklyn, a graduate of the Bellevue Hospital Medical College, New York, in 1870, a director of St. Vincent's Home for Friendless Boys, and a member of the New York State and Kings County Medical Societies, died at his home, from heart disease, on December 1, aged 70 years.

Dr. PATRICK HENRY BUMSTER of Long Island City, a graduate of the New York University Medical College, New York, in 1893, a member of the New York State and Queens-Nassau Counties Medical Societies, and the Greater New York Medical Association, and visiting surgeon to St. John's Long Island City Hospital, died at his home on December 1, aged 56 years.

Dr. LEWIS LANZER of Brooklyn, a graduate of the University of Tennessee, Medical Department, Memphis, in 1896, and a member of the National Eclectic Society, the Associated Physicians of Long Island, the Brooklyn Medical Society, and the German Medical Society, died at his home on December 3, aged 50 years.

Dr. EUGENE J. GALLAGHER of Yonkers, N. Y., a graduate of the Albany Medical College, Albany, N. Y., in 1892, and a member of the New York State and Westchester County Medical Societies, died at the Polyclinic Hospital, New York, from renal disease, on December 3, aged 46 years.

Dr. WILLIAM JOHN ROE of Philadelphia, a graduate of the Jefferson Medical College, Philadelphia, in 1895, attending otologist to the Philadelphia General Hospital, and a member of the Medical Society of the State of Pennsylvania, the Philadelphia County Medical Society, the Philadelphia Pediatric Society, and the Philadelphia Pathological Society, died in St. Mary's Hospital, Rochester, Minn., following an operation for tuberculosis of the Kidney, on November 28, aged 46 years.

Dr. NATHANIEL A. GRAY of Milwaukee, Wis., a graduate of the New York Homeopathic Medical College and Hospital, New York, in 1867, and a member of the State Medical Society of Wisconsin and the Milwaukee-Ozaukee Counties Medical Society, died at his home on November 25, aged 75 years.

Dr. JOHN LANG BRAY of Toronto, Ont., a graduate of the Medical Faculty of Queen's University, Kingston, Ont., in 1863, and from 1897 to 1914 registrar of the College of Physicians and Surgeons of Ontario, died at his home on November 24, aged 74 years.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

ROYAL SOCIETY OF MEDICINE—PARATYPHOID FEVER.

LONDON, Nov. 20, 1915.

AMID the always accumulating literature concerned with typhoidal diseases a number of experiments and observations have recently occupied our attention. The most important perhaps, certainly the most interesting, relate to paratyphoid fever; but this is not to be regarded as a mere variety of typhoid, for although it resembles that fever in its course and other features, a distinction has been established between the two diseases both clinically and pathologically. Paratyphoid is due to two distinct bacilli, which closely resemble the *B. typhosus* both as to their form and general characteristics, but they differ so much that they are considered specific microorganisms. Accordingly, we distinguish the cases and speak of them as "para A" and "para B." The former prevails in India, where it has been accurately described and its organism investigated by officers of the Royal Army Medical Corps. Its incidence is greater than generally supposed; it is transmitted by carriers, so that early diagnosis and isolation are important. Food poisoning is liable to be confused with it, and other mistakes in diagnosis may arise from neglect of or incomplete laboratory examinations.

Two officers of the Royal Army Medical Corps, Captain Torrens and Lieutenant Whittington, have contributed to the *British Medical Journal* what they call a preliminary note on the clinical aspects and diagnosis of the disease, a paper sufficiently full and interesting to excite anticipation of their further report. The B variety is well known here, though for a long time cases were not separated from simple typhoid, the milder cases of which are frequently diagnosed as para, and vice versa. The differentiation between them is of less importance practically than to mistake the fever for lesions of less consequence. The army medical officers mentioned above say that most of their patients either came from India or had been closely associated with troops of Indian divisions, though some had been Territorials or men of new batallions who had been attached to units from India, and this indicates that para A has been brought westward by our troops as carriers. It is admitted that paratyphoid fever may be so mild and atypical that its presence can only be esablished by thorough bacteriological examination though these same slight indications may justify treatment of suspects until a negative is proved, which can usually be done at the earliest stage. On the other hand, we may meet with such severe cases as closely resemble the gravest typhoid. It is the mild cases that are chiefly considered in the paper before us, and they are the most likely to be confused with influenza, "trench fever," and other diseases. Typical para B lasts from ten to eighteen days, para A three or four days longer, though the symptoms in this latter are usually milder. The common assumption that a case cannot belong to the enteric group unless it presents some "typhoid" appearance or abdominal disturbance is controverted in this paper: so is the very gradual onset of the text-books, the majority of patients not considering themselves ill until they report sick, though if pressed they may admit having been out of sorts a day or so before.

Some 60 per cent. feel ill three or four days, but 40 per cent. collapse in the course of their ordinary duties. A man gets headache, slight abdominal pain, with a couple of days' diarrhea, but does nothing, expecting it to pass away. The diarrhea does, but aching pains in back and head increase till the fourth day, when he succumbs. Such is typical of the group of 60 per cent. cases. In the other group (40 per cent.) a man may go to sleep feeling well and wake up with pain, feverishness, etc., rapidly increasing. The authors of the paper give the result of an analysis of 100 cases of para B and 50 cases of para A, from which it appears that eight symptoms occur in at least 20 per cent. at the outset; these are in the order of frequency: Headache (85 per cent.); diarrhea (55 per cent.); abdominal pain (35 per cent.); aching pains in the limbs (30 per cent.); shivering (25 per cent.); extreme general weakness (25 per cent.); backache (25 per cent.); epistaxis (20 per cent.). Summarizing these we may say that in a doubtful case the most important features to look for would be: An onset of about four days with malaise, pains in head, back and limbs, tendency to shiver, abdominal discomfort with a short period of looseness of bowels, soft pulse, which is remarkably slow in relation to the temperature, enlarged spleen (not necessarily palpable), fever lasting for a week to a fortnight. When a case can be seen from the beginning and a temperature chart kept it is easy enough at the end to say it has been typhoid or paratyphoid, but how seldom it is that we can so watch the patient. Probably by the tenth or twelfth day spots or other indications may come to our aid, but this may not be so, and we then only have the history to guide us. In a typical case a patient will say he has been out of sorts three or four days, and questions bring out that he has had shiverings more or less distinct, relaxed bowels, but only slight, there is some dullness and lethargy, tongue furred but red at edges or tip, abdomen tumid, perhaps slightly tender, as, too, the spleen; later constipation may develop, making enema appropriate. Temperature 101° to 102° at night, with morning remission of 2° or more. Small pulse, 70 to 80, very comprehensible. Such a case should be treated as paratyphoid, as it most likely will prove to be. All the complications seen in typhoid may be met with in paratyphoid. Two definite tendencies deserve attention: (1) toward involvement of the large bowel; (2) liability to pus formation. The former is accountable for perforations which may occur; the latter is seen in such complications as suppurative orchitis, abscess in spleen, liver, lung, etc. The death rate of paratyphoid is very low compared with that due to *B. typhosus;* para A under 1 per cent., and para B a little over 4 per cent.

A discussion on paratyphoid was begun at the Royal Society of Medicine on the 9th inst., and has been adjourned. It was opened by Dr. B. Dawson with a tribute to the excellence of the arrangements at the Stationary Hospital 14, which make it possible to pursue a research to the very end of every case, not merely establish a diagnosis by finding the organisms, but also—a much more serious matter—to make sure of its absence in other cases. A brilliant feature of this war, he held, was the small number of enteric cases, including in this term all infections by *B. typhosus* and by A and B paratyphoid. The existence of the disease at all was due to carriers (man or insect), for there had been no epidemic and no infection of food supply. This result, next to inoculation and good sanitation, he attributed to abundant good food and the consequent excellent nutrition of the troops. Professor Dreyer than gave an account of the work which had proved that the paratyphoid is a distinct clinical entity, and Colonel Sir Wilmot Herringham related his experience of trench fever, which is not really characteristic of the trenches, but seen in the combatant and medical units. He did not think it conveyed by lice, but rather by some other insect.

Progress of Medical Science.

New York Medical Journal.

November 27, 1915.

1. A Sanitary Study of Condensed Milk. William H. Park, M. C. Schroeder, and Paul Bartholow.
2. Climatic Inducements for the Overmature and Early Senescent. J. Madison Taylor.
3. Modern Infant Feeding. George Dow Scott.
4. Enlargement of the Thymus. Jacob Grossman.
5. Atrophic Rhinitis. William Ferguson.
6. Hematuria in Renal Neoplasm. Charles Denaclara.
7. The Nonsurgical Treatment of Exophthalmic Goiter Israel Bram.
8. Chronic Constipation in Infants. J. Epstein.

1. **Condensed Milk.**—William H. Park, M. C. Schroeder, and Paul Bartholow present a study of the bacteriological content and chemical analysis of the different varieties of condensed milk now on the market from which they conclude: (1) That the minimum standard for milk suitable for condensed milk should be definitely enforced. (2) That the present method of making condensed milk offers a wide latitude in preparation, and must of necessity offer a wide difference in the finished product. (3) That a considerable portion of the condensed milk has a high bacterial count because of growth of bacteria left alive by the heating process or added through contamination after it leaves the holder or vacuum pan. (4) That steps be taken to make standards which shall cover the following points: (*a*) Quality of milk to be used for condensing purposes as shown by bacterial and chemical tests. (*b*) The process of manufacturing condensed milk, including sanitary conditions. (*c*) The prevention of bacterial infection of the milk after it has been condensed. (*d*) Requirements, both chemical and bacteriological, of the finished product as offered to the consumer. (*e*) Statements on label of can which shall show the approximate percentage composition. Dr. Bartholow presents the clinical study from which he finds that the value of sweetened condensed milk depends upon the care and cleanliness used in manufacture, and that there is a want of evidence that the bacteria or chemical constituents are capable of affecting the health. However, the use of only the best quality of sweetened condensed milk is to be recommended for infant feeding. He also states that sweetened condensed milk has a place in infant feeding and gives his reasons for this statement.

5. **Atrophic Rhinitis.**—William Ferguson makes a plea in this paper for the performance of submucous resection in selected cases of atrophic rhinitis. He states that he has obtained most marked improvement, if not cure, in these cases by operative procedures, and that the results are sufficient to recommend such procedures even though the pathologist has not elucidated a scientific basis for operation in this condition.

6. **Hematuria in Renal Neoplasm.**—Charles Denaclara presents a statistical study based on 409 case reports of tumors of the kidney from which he concludes that hematuria occurs frequently in renal neoplasms, both in children and adults, and is more frequent in malignant than in non-malignant growths. In

the majority of cases of renal neoplasm blood is present in the urine during the entire duration of the process. An early hematuria should cause suspicion that the case is very probably one of neoplasm of the kidney of malignant type.

7. **Nonsurgical Treatment of Exophthalmic Goiter.**—Israel Bram relates his experience with 24 cases of exophthalmic goiter which convinces him that exophthalmic goiter diagnosed early is amenable to proper nonsurgical treatment in at least 75 per cent. of all cases. The only conditions, in his opinion, justifying surgical operations are dangerous pressure symptoms and evidences of malignant changes in the goiter. He finds that all cases do not respond to the same treatment, though some measures are applicable in all cases. The most important drugs in the treatment of this condition are quinine hydrobromide, suprarenal gland, iron, arsenic, phosphorus, preferably in the form of lecithin, and ichthyol. Rest, hyperalimentation, and electricity are essential adjuvants to a successful outcome. He states that a large majority of his patients are well on the way to recovery after six months' conscientious treatment as he has outlined it.

1. **Artificial Pneumothorax in the Treatment of Pulmonary Tuberculosis.**—Theodore B. Sachs reports the results obtained by twenty-four American observers and concludes that experience with artificial pneumothorax in the treatment of pulmonary tuberculosis is gradually modifying the sphere of its application. The trend is toward its use, regardless of the stage, in all progressive cases which fail, after sufficient trial, to respond to strict sanatorium regimen. Complications incident to the employment of this method, the great importance of continuous strict observation, and thorough clinical, laboratory, and Roentgen study of each individual case, the rest periods after each reinflation, the inability of outlining in advance the time of reinflations, in short, the close dependence of each successive step in pneumothorax therapy on the varying condition of the patient, are all factors which call, in the interest of safety and best results, for hospital or sanatorium supervision of each individual case in which the treatment is being applied. The present tendency, grown out of experience, is toward greater conservatism in the selection of cases. Through improvement of various details of technique and greater conservatism of action, pneumothorax therapy is gradually finding its definite place in the treatment of pulmonary tuberculosis which does not yield to other methods.

2. **Lesions of the Lumbosacroiliac Region.**—Harry Leslie Langnecker states that differentiation of the various types of these lesions is not difficult if one bears in mind the fact that in the traumatic group, injury with the sudden onset of symptoms is most important; in the static group, the defective posture with marked relaxation of the joints is present; and in the toxic group, the history of an inflammatory process with the tendency to fixation of the joints is found.

3. **Lymphoid Marrow and Tuberculosis.**—Leonard W. Ely presents an experimental study and states that in a paper read before the Section on Orthopedic Surgery, American Medical Association, San Francisco, John Fraser made the statement that red marrow was immune or practically immune to tuberculosis. This question is of great importance and they have been conducting a series of experiments in the laboratories of the Stanford School of Medicine to test the accuracy of Fraser's conclusions. He sums up the evidence to date as follows: (1) Tuberculosis is found only in those bones or regions of bones where lymphoid marrow is present. (2) Marrow tuberculosis is more common in children whose bones contain more red marrow. As age advances, marrow tuberculosis becomes rarer and less destructive. (3) After resections in adults, if secondary infection be avoided, the disease disappears. (4) Experiments show that lymphoid marrow is an excellent field for the growth of tuberculosis.

7. **Radium in the Treatment of Carcinoma of the Cervix Uteri and Vagina.**—Howard A. Kelly and Curtis F. Burnam base this report on a series of 213 cases of cancer of the uterine cervix and vagina treated with radium at the Howard A. Kelly Hospital between January, 1909, and January 1, 1915. Of these cases 14 were operable and 199 inoperable. Of the operable cases, 10 were operated upon and treated prophylactically with radium. Of these, 2 have been well for more than three years, 1 for more than two years, 4 for more than a year, and 3 for more than six months. These figures are quite suggestive when one considers that in 75 per cent. of all cases with operation there is recurrence and that 60 per cent. of these recurrences take place within one year following the operation. The total number of inoperable and inoperable recurrent cases is 199, of which 53 patients have been clinically cured, 109 markedly improved, and 37 not improved. Their series includes 35 cases of originally inoperable cancer of the cervix uteri or vagina in which the patients were clinically cured—in 2 cases for over four years; in 2 cases for over three years; in 4 cases for over two years; in 17 cases for over one year; in 10 cases for over six months. Excluding the operable cases, in which they had both operated and used radium, there were 203 cases left; in 57 of these the patients were clinically cured. One had lasted for six years; 3 for over four years; 4 for over three years; 5 for over two years; 29 for over one year, and 15 for six months. The authors feel convinced that radium is of exceedingly great value in the treatment of cancers of the cervix uteri and vagina. They believe that every inoperable cancer of the cervix uteri or vagina, provided general metastasis is not evident, stands a chance of at least one in four of cure by the radium treatment; and that this ratio in operable cases may be raised to three to four or better.

8. **The Action of Radium on Cancers of the Pelvic**

Organs.—Henry Schmitz reports that since April, 1914, he has treated 112 cases of malignant growths of various regions of the body with radium. Forty-eight of these were pelvic tumors and 41 are considered in this paper. Twenty-four of these cancers were inoperable, 9 recurrent, and 8 operable. He found that inoperable cancers that were not far advanced so that cauterization was not contraindicated, yielded satisfactorily to radium therapy and that advanced inoperable and recurrent cancers were ordinarily refractory toward the radium rays. Any improvement noted was at least very temporary. The patients treated with the rays after surgical removal of the organs did well, although in these cases the time which has elapsed since the treatment averages only eight months. The writer believes that patients suffering from cancer should be treated surgically and then radiologically, and that if surgery is contraindicated they should receive radium treatment, which at least relieves the subjective symptoms and often the objective ones. While the clinical and histological studies show that radium rays are a valuable addition to the therapy of cancer, it will require years of constant observation to demonstrate such results as anatomical cures.

10. Radiant Energy.—Everett S. Lain attempts a classification of skin diseases with reference to their histopathology and etiology which he believes will enable one to study the methods of treatment by radiant energy more intelligently. Under the first division he places diseases whose etiology is yet unknown though they are supposed to have their origin in some toxic product, such as dermatitis herpetiformis, the different varieties of erythemas, the lichens, psoriasis, etc. Under the second division he places those diseases which appear to be an inexplicable derangement of the superficial glands, or nerves, or of metabolism within cells, such as hyperhydrosis, pompholyx, pruritus, prurigo, herpes zoster, etc. In the third class are placed those diseases which are superficial in origin, such as staphylococcic and streptococcic infections. In the fourth class are all those diseases characterized by an increased development of pathological cells, whether of a benign or a malignant nature. In the first and second classes radiotherapy locally applied may give some temporary relief and may be recommended only as an aid to dermatological therapy. In that class of skin diseases chiefly local in origin radiotherapy has proved more satisfactory than any other mode of treatment. In the fourth class of cases the author has had very uncertain results in the treatment of different kinds of sarcomas. On the other hand, the treatment of superficial epitheliomas before the stage of metastasis has been very satisfactory, giving in a series of 162 cases 91 per cent. of apparent cures in that the patients are still alive and show no signs of recurrence.

11. Treatment of Fractures.—J. W. Cokenower states that all the fractures that can be adjusted manually and can be fixed in a position that will insure a good functional result, even though the Roentgen ray shows lack of perfect end-to-end approximation, are to be treated by the closed method. In all fractures with marked deformity, such as overlapping, angulation, lack of contact of fractured surfaces, evidence of soft or detached osseous tissue between the ends—of the bones, and especially compound fractures when it is apparent that union will not take place, the open method is invariably used. When the open method is used the writer prefers Lane's plates when sufficient smooth bone surface can be obtained for their attachment. When this cannot be done he prepares the ends of the bones for good and satisfactory apposition. If the bones are not sufficiently jagged he makes one lateral and one anteroposterior dovetail in the ends of the bones, after which he wires them. He believes that the bone graft inlay should always be used in nonunion, especially when the pathological softening of the ends of the bones is augmented by infection or displacement of the ends, including soft tissue between them, but it should not be used in simple fresh fractures. No rule can be made for the use of plaster of Paris and splints, except that the former should not be used when any swelling is present and should never be left in too long, but splints when properly made and adjusted are always satisfactory. One should always take advantage of whatever help the Roentgen ray can give in connection with the treatment of fractures.

13. The Stability of the Infusion of Digitalis.—Robert A. Hatcher and Cary Eggleston conclude that the infusion of digitalis is fairly stable when prepared and kept with ordinary care, no important change then occurring within a week. The addition of alcohol to the infusion is unnecessary. Old, and even moldy, digitalis and its infusion may give the typical digitalis actions qualitatively so long as they retain any considerable degree of activity. A properly made infusion of digitalis represents the leaf practically in its entirety, the action being qualitatively like that of the tincture. Owing to the variability in activity of the infusion as it is commonly obtained, the tincture should be preferred to it in therapeutic practice.

6. A Case of Oral Sepsis. Adolph Abrahams.
7. Zinc in Potable Water. Has It Any Effect Upon Health? John C. Thresh.

1. Wound Infections and Their Treatment.—Almroth E. Wright delivered this lecture at the opening of an Exhibition of Surgical Appliances for the Treatment of the Wounded, held at the Royal Society of Medicine from October 8 to 14, in which he gives a very comprehensive review of the methods hitherto used in the treatment of wounds. He states that before the war it was generally held that for the conduct of wound infection all that would be required would be to drain the wound, by making an opening at the most dependent point, then to wash it out with antiseptics, and finally to apply dressings. It was also thought that for the proper carrying out of this procedure any doctor who was on the Medical Register, or any trained nurse would suffice. Now the wind has swept all this away and it has come home to everybody that every wound is infected and that the infection is the really serious element in the wounds. Practically everybody has also become aware that the antiseptic system so far as the treatment of wound infection is concerned has completely broken down. The lecturer presents a scheme for the phylacacogic treatment of wound infections, following the different steps of treatment, in the field ambulance, at the casualty clearing station, and at the base hospital. The program includes irrigation with hypertonic salt solution (the physiological action of which, its effects and the indications for different strengths of the solution are discussed in detail) until the tissues are restored to their natural condition and there is merely surface infection. The wound is then irrigated with physiological salt solution until thé surface infection is extinguished or nearly so, and then the secondary suture of the wound is undertaken in one

or a series of successive operations. In concluding, the author urges a reorganization of hospital forces which will place a responsible head over a staff of men with both laboratory and clinical experience who will be deputed, one to each hospital, to exercise supervision as "physician in charge of wounds" over all that department of treatment which lies outside the sphere of operative surgery.

3. **Gunshot Injuries of Peripheral Nerves.**—Wilfred Harris states that although there is nothing new in the gunshot injuries of nerves in the present war, yet the large number of cases available for examination has impressed upon him several facts and has afforded opportunities of demonstrating the areas of sensation supplied by the various peripheral nerves. These facts are the importance of an accurate history of the details of the wound or wounds and of the immediate effects and the importance of a careful and methodical examination of the paralysis, both motor and sensory, in order to determine whether it matches with the known anatomical distribution or one or more nerves, or of a portion of a plexus, or whether it resembles the phenomena produced in hysteria. Careful charts of the sensory loss are more important than the presence of complete muscular paralysis, with reaction of degeneration, in estimating the severity of the injury of a mixed nerve. The various stimuli used in testing by hard or light pressure, pin-prick, scratch, camel-hair brush or cotton wool, are tests of different degrees of conductivity of the nerve, not of different systems of fibers. Hard pressure will still be perceived except in total interruption of the nerve conductivity by actual division or by its inclusion in a dense scar. Commencing recovery of sensation may in some cases be observed within a few days only of the secondary suture of the nerve. The sensation of the limb may vary from day to day within narrow limits, or according as the limb is warm or cold.

4. **Gunshot Injuries to the Peripheral Nerves.**—R. H. Jocelyn Swan reports on 63 cases of gunshot injury to peripheral nerves, of which 38 were operated upon, involving the exploration of 41 individual nerves. Thirteen cases showed complete anatomical division of the nerves. In cases of complete nerve division there is but one procedure to adopt—the ends must be dissected free, the bulbous proximal end removed until the nerve bundles can be seen, a small part of the distal end must be resected, and the two ends must be accurately joined. In cases in which the nerve is firmly embedded in scar tissue, the best thing to do is to resect the fibrous portion and join the two ends by accurate suture. The treatment of these cases does not end with the operation, but must be continued by such means as massage, electrical stimulation, and passive movements to the joints. In 17 of the author's cases voluntary muscle action returned at a date varying from six weeks to seven months. In cases in which the nerve had been completely divided and the ends freshened and joined improvement has been definite in four months, while sensation has returned earlier. In 15 cases operated upon four months ago no improvement has yet been noted, but probably sufficient time has not yet elapsed. The author has observed that voluntary action may return in previously paralyzed muscles some weeks before any reaction can be obtained by a strong Faradic current, although with the Lewis-Jones condenser a reduction in the stop from No. 10 to No. 5 or 6 has been found with the muscular return.

7. **Zinc in Potable Water.**—John C. Thresh says he has been consulted on a number of occasions as to the effect on health of small quantities of zinc in potable waters. He finds small quantities of zinc in all water conducted by galvanized ironpipes, but that statements made about the injurious effect of small quantities of zinc are entirely without foundation. In every sample of water which the writer has examined the zinc has been found in solution as bicarbonate. The whole is thrown out of solution by continued boiling. Evidence seems to show that zinc is quickly eliminated from the system and furthermore it is stated that the bicarbonate is devoid of poisonous properties.

7. On Wound Infections and Their Treatment. Almroth E. Wright.

1. **Paratyphoid Fever.**—J. A. Torrens and T. H. Whittington give the result of their impressions received while observing some three or four hundred cases of paratyphoid fever in hospital among the troops in France. The great majority of the patients came from India. Paratyphoid A fever has been rare in England and Western Europe and hence it seems probable that this type has been implanted among the troops by carriers from abroad. They find it more than unprofitable to attempt to discriminate clinically between paratyphoid A and paratyphoid B. One fertile source of error seems to be the assumption that a case cannot be one of the enteric group unless it presents a more or less "typhoid" appearance, or at any rate some abdominal disturbance in the direction of pain or diarrhea. After discussing the clinical symptoms in detail the writers state that in a doubtful case the most important individual features are probably: 1. An onset of about four days with malaise, pains in the head, back, limbs, a tendency to shiver, and abdominal discomfort, with a short period of looseness of the bowels. 2. A soft pulse which is strikingly slow in relation to the temperature. 3. An enlarged spleen, not necessarily palpable. 4. A fever lasting upward of a week or fourteen days. It is possible for paratyphoid fever to show all the complications and sequellae which are found in typhoid fever. There is, however, a marked difference, both actual and relative, in the frequency with which they occur in the two diseases. Attention is called to what seems to be two definite idiosyncracies of paratyphoid B: The first is a tendency to involve the large gut, and the second, a liability to pus formation, as shown by complications of a suppurative nature. The mortality from paratyphoid B was a little over 4 per cent. and of paratyphoid A a little under 1 per cent. in this series. The authors discuss the routine measures which must be adopted in order to place the diagnosis of a suspected case on as sure a basis as possible. A positive diagnosis can be made in one of two ways. First, the specific bacillus may be recovered from the blood, feces, or urine of the patient, and secondly, evidence may be discovered in his blood that he has acquired or is acquiring an immunity to a specific infection.

3. **Typhoid + Paratyphoid A + Paratyphoid B + Cholera.**—Aldo Castellani and Ralph W. Mendelson relate their somewhat extensive experience in Serbia with the tetravaccine, typhoid + paratyphoid A + paratyphoid B + cholera, which has also been used by one of the authors in Ceylon. They review the repara-

tion of the vaccine and the animal experiments which have formed the basis of the work and describe the technique of the inoculation. They state that the inoculation of the tetravaccines is harmless. They have had no septic or other accident in any of the more than 50,000 men that they have inoculated, which has entailed more than 100,000 injections, nor have they heard of any untoward accident from their colleagues who have vaccinated more than 120,000 men in Serbia with the tetravaccine. They have never observed any really serious reactions, either local or general. The inoculated persons develop protective substances for the four germs. The amount of agglutinins present for each of the four germs is practically the same as in control individuals, inoculated with typhoid paratyphoid A, paratyphoid B, and cholera monovaccines. They are of the opinion that tetravaccines should be used as a matter of routine to inoculate the troops taking part in the present war.

5. **Treatment of Amebic Dysentery.**—George C. Low states that he has been seeing many cases of dysentery in the Seamen's Hospital, and, after pointing out the difficulties attendant upon the administration of emetine by the mouth, recommends in acute cases of amebic dysentery in bed injections. In chronic cases with slight local lesions that one does not wish to keep in bed the mouth method may be employed. He uses one grain of emetine hydrochloride for each injection, two of these being given daily night and morning for the first two or three days if the case is a bad one with much blood, mucus, and pain. After that he gives a one-grain injection every night until 12 grains in all has been given. By this time all blood and mucus should have disappeared, and amebae should no longer occur. Sometimes a second course of injections may be necessary, but this need not be as long as the first, one grain until six grains have been taken usually sufficing.

Berliner klinische Wochenschrift.

October 18, 1915.

Influence of Filtered Roentgen Rays on Skin Diseases.—Meyer sums up the advantages of this mode of treatment as follows: In many diseases results are more prompt and certain than with other methods, and this is especially the case with chronic affections, while the damage done to the skin is trivial, because it becomes somewhat more sensitive to the rays. Dermatoses which have been pronounced incurable have been cured by this method, or only at the expense of severe injury to the skin. The chance of a reaction with filtered rays is small, and when reactions follow radiation, they pursue a mild course. Since large *x*-ray tubes are required when filtered rays are used, a correspondingly large surface of integument can be rayed at one time. The possibility of a stronger charge makes it possible to reach the intended dose in shorter time. The pains and time required for protection against unfiltered rays are greatly diminished. Finally, there is no longer—with filtered rays—any necessary distinction between superficial and deep radiation.

Experience with Infectious Diseases in the Army.—Grundmann has found antitoxin valuable in tetanus when given in the prodromal stage and when the first symptoms have developed—local tetanus, painful contractions and rigidity, hyperesthesia, sweating, etc., etc. He extends prophylactic injections to those soldiers who have slept with tetanus comrades. When the disease has developed he pushes both antitoxin and magnesia until the muscles relax. His mortality has been from 55 to 65 per cent. He saw sporadic cases of diphtheria in soldiers, and these were all severe in type, as the already overstrained heart was deeply influenced by the disease toxin. The cardiac weakness was readily perceived in the livid extremities and pressure points, hemorrhages, etc. The patients who had had the disease for several days received massive intravenous doses of antitoxin. There was one case of severe anaphylactic shock requiring camphor injections and artificial respiration. A few cases of measles seen included one of the hemorrhagic type which had been sent in as a typhus suspect. The presence of Koplik's spots and other symptoms readily led to the correct diagnosis. Scarlet fever was somewhat more common than measles. Of thirty cases treated none ended fatally. One patient with a mere roseola was mistaken at first for a typhus case. The so-called "second outbreak" (Pospischill) which comprises nephritis was not seen. But five cases of erysipelas were seen, none severe. Tuberculosis appeared under the strain of war in those of tuberculous stock or habitus. Cases of miliary tuberculosis were readily mistaken for typhoid. One of the patients recovered. The diagnosis was made in part by exclusion, but there was a tuberculous exanthem and the *x*-ray showed disease foci in the lungs. There was no sputum. The genesis of the disease was doubtless as follows: a hydrocele, evidently tuberculous, had been operated upon, with probable infection of the veins. The author saw a few cases of cerebrospinal meningitis in both the fulminant and ordinary acute types. The former is always fatal.

Münchener medizinische Wochenschrift.

October 19, 1915.

Treatment of Venereal Buboes with X-Rays.—Kull states that the chancroid is a mild affection *per se* and is only to be feared as a possible cause of bubo. The original treatment of the latter was poulticing followed by incision, this being ultimately followed by free incision and curettage, or extirpation of the lymph nodes. There is a closed or semi-closed treatment of these buboes which agrees with that for suppurating tuberculous lymphnodes. Owing to the power of the *x*-rays over the latter the author made a test of them in chancroidal bubo. They applied these both before and after suppuration. In the former class of cases the action of the rays is startling. The pain at once ceases and the nodes soon resume their normal size. This result may come about after one radiation, the patient being practically well within 48 hours. If the bubo has not become a great abscess the rays are able to destroy the leucocytes, which are probably absorbed. All signs of inflammation cease and the indurated infiltration is slowly absorbed. When an abscess has formed it should be evacuated by puncture, after which it will yield to the rays. Syphilitic buboes promptly subside under the rays. These results are only what should be expected, the author says, when we consider the power of the rays over tuberculous lymph nodes and lymphoma.

Two Cases of Swallowed False Dentures Treated with Apomorphine.—Gerstein, a marine surgeon, reports the case of a stoker who swallowed a plate with four incisor teeth in his sleep. The object could neither be seen nor felt with forceps. Three hours before he had eaten heartily. The author at once gave him an injection of apomorphine and placed him in the best possible position for vomiting (prone position, neck stretched and forehead supported. In five minutes came the first retch. The next in order brought away the teeth. Vomiting lasted 12 minutes. The second case was a duplicate of the first.

Insurance Medicine.

Meaning of "Abortion" in Insurance Policy.—In an action on a policy of insurance which exempted the insurer from all claims resulting from an abortion, the evidence showed that the death of the fetus, which caused the insured's death, was the result of an assault upon her by her brother-in-law about two weeks before her death. It was held that the waiver in the policy referred to an act done intentionally and unnecessarily, for the purpose of procuring an abortion. As ordinarily used among laymen and married women, "miscarriage" is understood to mean failure on the part of a woman, from causes beyond her control, to carry a fetus to maturity; while "abortion" is understood to mean the intentional causing of a miscarriage. Judgment for the plaintiff was therefore affirmed, on the ground that language used in a contract prepared by one of the parties thereto, which is susceptible to more than one construction, should receive such a construction as the party preparing the contract at the time supposed the other party would give to it, or such a construction as the other party would be fairly justified in giving to it.—Flory v. Supreme Tribe, Nebraska Supreme Court, 152 N. W., 295.

Inaugurating the Life-saving Campaign.—Mr. Frederick A. Draper in discussing Dr. Blackford's paper read before the fifth mid-year meeting of the Medical Section of the American Life Convention, said the adage, "An ounce of prevention is worth a pound of cure" had a very pertinent application to the subject under discussion. It should be considered not only in its relation to the discovery of diseases, already present, but in the prevention of diseases, particularly those resulting from improper methods of living. We had ample statistics demonstrating the increase in diseases of the heart, kidneys, and liver. The decrease in the mortality rate resulting from infectious diseases was offset to a considerable extent by the increase in rates just mentioned. While a decrease in certain diseases must be followed by increases in others, when considered in ratios, since all must eventually die, the increase in the mortality of certain diseases was of greater intensity and was found at younger ages than was fully explained by the decrease in others. What causes were operating, therefore, to produce these higher mortality rates; and were preventive measures possible and feasible? Mr. Draper answered this question by attributing the change in the mortality rates to modern modes of living which he sketched at length.

He said that the field directly open to insurance companies would seem to be restricted to the policyholders, but this was quite large enough, and the benefits were so immediate and extensive as to warrant careful study of the methods to be developed.

For the purpose of having the subject more adequately considered, he would suggest that the Section arrange for a special committee to consider methods for educational work, and if found expedient to report plans for interesting the life-insurance companies in joint endeavor. Such a committee in connection with similar committees from the Legal Section and the whole convention could formulate bills to be presented to Congress and the several States providing for the publication and distribution of manuals and for such other national and State legislation as might be found suitable and desirable. It could also arrange for cooperative work with other organizations, such as the U. S. Public Health Service, the "Live-a-Little-Longer" movement could be assisted, etc. The benefits that would follow such well-directed effort as would be possible to such a committee would be far-reaching in their scope.

The Life-Saving Movement.—Dr. M. O. Devaney, Medical Director Indianapolis Life Insurance Company, Indianapolis, Ind., in discussing Dr. Blackford's paper read before the fifth mid-year meeting of the Medical Section of the American Life Convention, said that some plan whereby people in general of all classes, could be taught and impressed with the advanced ideas of disease prevention would probably be more successful than a too great reliance on the movement outlined by Dr. Blackford, advanced by the insurance companies and policyholders. Theoretically, it seemed easy; but practically it was a tremendous proposition. People were slow to reform. They were slow to leave old ways of living. The ordinary health laws, irrespective of the efforts of the health officers, were violated continually. He repeated that progress had been slow up to the present, and it seemed to him that if they were in earnest, and wanted disease prevented and lives made longer, they must build a machine or organization, one that would bring the teaching of disease prevention and the right principles of living down to the individual family.

Medical Examiner's Report Contradicting Proofs of Death.—In an action on an insurance policy the plaintiff introduced in evidence, as tending to contradict and explain the statement of the attending physician in the proofs of death that the insured not only died of tuberculosis, but was suffering therefrom several weeks before the application for the insurance was made, the report made by the insurance company's medical examiner in connection with and attached to, the application for the insurance, in which it appeared that the examiner personally inspected the life insured and examined the subject to ascertain his fitness therefor. This report recited that the examiner had examined the insured's respiratory organs and found them in all respects sound, and that he possessed sound health and a good constitution. This, it was held, was competent and sufficient evidence to support a finding of the jury that the insured made no misrepresentation in obtaining the policy.—Clarkston v. Metropolitan Life Ins. Co. (Mo.), 176 S. W. 437.

General Statement of Examining Physician Not Contradictory of Positive Evidence.—In an action on a policy of insurance two disinterested medical witnesses testified that the insured suffered from tuberculosis at the time of application. Against this there was nothing but the general statement of the examining physician, not subject to cross-examination, that the insured appeared to be in good health, and recommending him as a good risk, which might all be true, and yet the tuberculous condition be present, as testified to by the other physicians. The examining physician's statement was in effect mere negative evidence of fairly persuasive collateral facts, which, in the absence of any other evidence, would sustain an inference that tuberculosis did not exist, but, in the presence of unimpeachable and certain affirmative evidence that it was in fact found to exist, was not sufficient to sustain a verdict, because it did not necessarily contradict such affirmative evidence.—McKnelly v. Brotherhood of American Yeomen, Wisconsin Supreme Court, 152 N. W. 169.

Book Reviews.

THE MEDICAL RECORD VISITING LIST, OR PHYSICIANS' DIARY FOR 1916. Newly revised. Price, $1.50. New York: William Wood & Company.

EVERY physician uses a visiting list; and the handsome volume before us fulfills all the requirements of even the most exacting. In addition to the ruled pages for the record of daily visits, the book contains a calendar, pregnancy table, dose table, notes on artificial respiration, signs of death, and the writing of wills. There are also blanks for the entry of consultations, obstetric engagements, confinements, vaccinations, deaths, cash accounts, and the addresses of nurses and patients. The book is of handy size, with paper of good surface and well adapted for the use of either pencil or ink.

THE PHYSICIAN'S VISITING LIST (Lindsay & Blakiston's) for 1916. Sixty-fifth year of its publication. Price, $1.25 for twenty-five patients. Philadelphia: P. Blakiston's Son & Co.

THIS popular visiting list, which has supplied the needs of several generations of medical practitioners, comes again with the close of the year to gladden its old friends and to appeal for approval to the army of young physicians just out of college or hospital and entering upon their life work. For the latter the twenty-five patients list will be ample, but if their hopes are high they may be glad to know that the book is made in sizes for 50, 75, or even 100 patients per day or week, so that having once begun its use they will not be forced to change when their practice assumes its expected proportion. The book is supplied with the usual reading matter, for emergency use, of incompatibles, treatment of poisoning, metric system of weights and measures, dose-table, etc. There are also blank pages for obstetric engagements, addresses of patients, cash account, and memoranda.

TEXTBOOK ON NERVOUS DISEASES. By G. ASCHAFFENBURG, Cologne; H. CURSCHMANN, Mayence; R. FINKELNBURG, Bonn; R. GAUPP, Tübingen; C. HIRSCH, Göttingen; FR. JAMIN, Erlangen; J. IBRAHIM, Munich; FEDOR KRAUSE, Berlin; M. LEWANDOWSKY, Berlin; H. LIEPMANN, Berlin; L. R. MÜLLER, Augsburg; H. SCHLESINGER, Vienna; S. SCHOENBORN, Heidelberg; H. STARCK, Karlsruhe; H. STEINERT, Leipzig; CHARLES W. BURR, Philadelphia. Authorized English edition. Edited by CHARLES W. BURR, B.S., M.D., Professor of Mental Diseases in the University of Pennsylvania; Neurologist to the Philadelphia General Hospital. In two volumes; 246 illustrations. Price, $12. Philadelphia: P. Blakiston's Son & Co., 1915.

THIS work, paged as a single volume contains 1132 pages, and as its title page implies, is virtually a cyclopedia of neurology. It is published as Curschmann's "Textbook of Nervous Diseases," although Curschmann's name is not mentioned anywhere as editor nor is it signed to the preface. Dr. Burr, in addition to his editorial functions, contributes a chapter on neurasthenia, psychasthenia, hysteria, and borderland states. The German sponsor, Dr. Curschmann, contributes the sections on the myopathics, and vasomotor and trophic disturbances. The first impression that one obtains from glancing through the work is that the contributors, while very far from unknown to the American public are not as a rule of the highest eminence, no less than seven being privat docents. Professor Krause, the distinguished brain surgeon, is of course not included among the neurologists proper. Aschaffenburg and Lewandowsky have themselves edited large works on neurological subjects and in general have shown vast literary activities. The former furnishes a section on the identical topics covered by Dr. Burr and the reason for this duplication is not apparent; the latter makes no allusion to it.

TRANSACTIONS OF THE AMERICAN PEDIATRIC SOCIETY. Twenty-sixth Session held at the Red Lion Inn, Stockbridge, Mass., May 26, 27 and 28, 1914. Edited by LINNAEUS EDFORD LA FÉTRA, M.D.

THERE are twenty-nine contributions to this volume, presenting a wide range of subject-matter in pediatrics. Among these may be mentioned the articles on "The Artificial Cooling of Sick Rooms in Summer," by H. Heiman; "Recurrent Vomiting," by C. G. Kerley; "Typhoid Fever in Children," by H. D. Chapin; "Diseases Connected with Meckel's Diverticulum with Special Reference to Diverticulitis," by J. P. Crozer Griffith; "The Pathogenesis and Prophylaxis of Rickets," by J. E. Winters; and "Endocarditis in Children," by F. M. Crandall.

REPORTS FROM THE LABORATORY OF THE ROYAL COLLEGE OF PHYSICIANS, EDINBURGH. Edited by J. J. GRAHAM BROWN, M.D., and J. RITCHIE, M.D., Vol. XIII. Edinburgh: Oliver and Boyd, 1915.

THIS volume comprises contributions made during 1913 and 1914 in the fields of protozoology, anatomy, biological chemistry, pathology, and bacteriology. There are four articles by J. P. McGowan dealing with the relation of sarcosporidia to the disease in sheep called "scrapie." Among the articles in the section on pathology may be mentioned those dealing with "A Comparison of the Lesions of the Nervous System in Distemper of the Dog with those of Human Poliomyelitis," by J. P. McGowan and J. W. Dawson; and a series of three articles by J. P. McNeil dealing with the relation of scrofula, acutely fatal illness, and anaphylaxis to the status lymphaticus. In the section on bacteriology there is a series of important articles, by A. P. Mitchell, concerning tuberculosis of the lymph glands, in children, and infection of children with the bovine tubercle bacillus.

DIFFERENTIAL-DIAGNOSTISCHE TABELLEN DER INNEREN KRANKHEITEN. Von Dr. med. J. CEMACH, Wien. 46 Tabellen mit farbigen und schwarzen Abbildungen sowie 8 Fiebertypen. Zweite, vermehrte und verbesserte Auflage. München: J. L. Lehmann's Verlag, 1915.

IN the second edition of this little volume the author added 12 differential tables and revised many of the older ones. Altogether the book contains 46 tables and 18 illustrations, some of them colored to aid in making the tables more easily understood. The author states that it was not possible for him to consider all possibilities in taking up a definite disease entity, hence he confines himself to the common and typical diseases. This little book of pocket size, bound in flexible covers, will be of help to practitioners who want to refresh their memories on the differential points of the more common diseases.

EXERCISE IN EDUCATION AND MEDICINE. By R. TAIT MCKENZIE, B.A., M.D., Professor of Physical Education and Director of the Department, University of Pennsylvania; Fellow of the College of Physicians of Philadelphia and of the American Academy of Physical Education; President of the American Physical Education Association, 1913-1915; President of the Society of Directors of Physical Education in Colleges, 1912; Sometime Lecturer in Anatomy and Medical Director of Physical Training at McGill University; Lecturer in Artistic Anatomy, Montreal Art Association, Harvard Summer School, and Olympic Lecture Course, St. Louis, 1904; M. P. E. Springfield College; Second Edition, Thoroughly Revised. With 478 Illustrations. Price $4.00 net. Philadelphia and London: W. B. Saunders Company, 1915.

THIS work comprises two parts, of which the first deals with exercise in education and the second with exercise in medicine. The introductory chapter defines and classifies the various exercises, and their physiological aspects are discussed in chapters on the behavior of the muscles and the lungs during exercise; the estimation of heart efficiency; the effects of exercise on the heart; the control of movement, nutrition, and excretion during exercise, and exercise in relation to age, sex, and occupation. The German, Swedish, and French systems of gymnastics are described in detail. Then follow chapters on physical education by athletics; physical education in Young Men's Christian Associations, and camps, Boy Scouts, Camp-fire Girls; municipal playgrounds and baths; physical education in schools, colleges, girls' schools, and women's colleges, the physical education of the blind and deaf-mute, and of mental and moral defectives. Part II includes chapters on the application of exercise to pathological conditions, massage, and vibration; treatment by exercises of flatfoot and clubfoot, deformities of the spine, abdominal weakness, visceroptosis, respiratory diseases, diseases of the circulation, obesity, and nervous disorders. The book is profusely illustrated chiefly with reproductions of photographs. It is an interesting and scientific exposition of a subject whose importance in education and medicine is now being given full recognition. The physician will find this book of eminent practical value.

Warp and Woof. By L. Pierce Clark. Riverside, Conn.: Hillacre Bookhouse, 1915.

One takes up this volume of short poems hardly knowing what to expect from the pen of a man who has devoted his medical life to the study and cure of epilepsy. After reading, there is borne in upon the mind and heart the fact that these poems, short as they are, display a depth of understanding of life astounding in its intellectual and emotional comprehension. They are prismatic, reflecting the rays of joy, pathos, humor, hope, despair, and love in rhythmical, liquid English. That there is an undercurrent of sadness through many of the poems is not to be wondered at, for the writer must come in contact with the fatalistic side of life, while such a poem as "The Forbidden Guest" and "The Psychoanalyst" give evidence of the influence of the Freudian outlook on human nature. "Convalescence," "The Paranoiac," "The Epileptic Crisis," and "The Master of the Clinic," are among his contributions to his work; "The Night Born," "A Christmas Jingle," "The Nuns," "How Love Dies," and "The Immutable" show his fellow touch.

Modern Biologic Therapeusis. A Concise and Practical Treatise on Biologic Products for the Use of Practitioners in the Modern Application of Immunology to Therapeutics. From the Medical Department of the Lederle Antitoxin Laboratories, New York. Cloth Binding. Illustrated. Price, $1.00. New York: Press of Joseph D. McGuire, 1915.

In this little book there are about three hundred pages of definite, scientific information on the history, use, dosage, and most approved methods of administration of vaccines and sera prepared by the Lederle laboratories. The field of vaccine and serum therapy is covered in an interesting, yet simple and direct manner, the information being based on the latest investigations and soundest scientific teachings. The illustrations include photomicrographs of the more common bacteria and half-tone reproductions of some of the men famous for their work in this field.

Die nichtgonorrhoische Urethritis beim Manne, von Professor Dr. C. Adrian. Price, 1.80 mark. Halle a S.: Carl Marhold, 1915.

The author considers sterile urethritis and urethritis due to bacteria other than Neisser's gonococcus, including experimental forms. He has produced within small compass a very superior monograph.

The Principles and Practice of Obstetrics. By Joseph B. DeLee, A.M., M.D., Professor of Obstetrics at the Northwestern University Medical School; Obstetrician to the Chicago Lying-In Hospital. Second edition. Price, $8.00 net. Philadelphia and London: W. B. Saunders Company, 1915.

The justification of a textbook which treats pregnancy as a disease and emphasizes the pathological side of obstetrics is found in the fact that a second edition of this work has become necessary after a lapse of only two years. This is all the more remarkable when one considers the size and the cost of the work. There is no more complete and elaborate presentation of the subject in the English language than is found here and the new edition has been so thoroughly revised that it is very largely rewritten. The author's opinion of "twilight sleep" is a very sane one and deserves wide publicity. The illustrations are numerous and excellent. The one criticism which might be made is in the price. The purchasers of the first edition must be annoyed to find that such an expensive work is good for only two years. How much more beneficial to the profession at large it would be to print the book on cheap paper with fewer and poorer illustrations. Then when the necessity for revision appeared all physicians interested in obstetrics would be willing and could afford to buy each new edition as it appeared. However such enterprise is hardly to be expected in this country. In the meanwhile the work is a necessity to the obstetrician and will be of the greatest value to all physicians who practise obstetrics.

A Compend of Medical Chemistry, Inorganic and Organic, Including Urinary Analysis. By Henry Leffmann, A.M., M.D. Professor of Chemistry in the Woman's Medical College of Pennsylvania and in the Wagner Free Institute of Science. Sixth edition, Revised. Price $1.00. Philadelphia: P. Blakiston's Son & Co., 1915.

In the preface to this and the preceding edition of this compend is the following: "In the present system in professional schools, students are obliged to meet two distinct requirements. They must study for the knowledge necessary for the practice of the profession and they must study to pass examinations. The latter are in so many cases arbitrary in scope, and affected by the personal equation of the examiner, that the student cannot be blamed for resorting to a concise presentation of the more important facts of the science, supplementing this by notes of the narrower and more strictly personal items of the teaching." This is undoubtedly true, and it is more true of chemistry than of any other subject in the medical curriculum. On the strength of this, we would strongly advise all the medical students attending Professor Leffmann's lectures to procure this volume.

Progressive Medicine. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D., Professor of Therapeutics, Materia Medica and Diagnosis in the Jefferson Medical College, Philadelphia; Assisted by Leighton F. Appleman, M.D., Instructor in Therapeutics, Jefferson Medical College, Philadelphia. Price $6.00 per annum. Philadelphia and New York: Lea & Febiger, September, 1915.

The present instalment of this well known publication contains a summary of the following branches of medicine: Diseases of the thorax and its viscera, including the heart, lungs, and blood vessels, by W. Ewart; Dermatology and Syphilis, by W. S. Gottheil; Obstetrics, by E. P. Davis, and Diseases of the Nervous System, by W. G. Spiller. All of these writers have been contributing to this publication for several years, a fact which ensures a valuable continuity from year to year which is not often found in works of this kind.

The Ophthalmic Year Book, Volume XI., Containing a Digest of the Literature of Ophthalmology for the year 1914. Edited by Edward Jackson, M.D., Sc.D., Professor of Ophthalmology in the University of Colorado. Assisted by Theodore E. Schneideman, M.D., Philadelphia; William Zentmayer, M.D., Philadelphia; William H. Crisp, M.D., Denver; Casey A. Wood, M.D., Chicago; Wendell Reber, M.D., Philadelphia; Harry S. Gradle, M.D., Chicago; Robert Henry Elliot, M.D., London; Hugo W. Aufwasser, M.D., Denver; Meyer Wiener, M.D., St. Louis; Will Walter, M.D., Chicago; Florence Mayo Schneideman, M.D., Philadelphia; Nelson Miles Black, M.D., Milwaukee; Charles Zimmermann, M.D., Milwaukee, and Thomas B. Holloway, M.D., Philadelphia. Illustrated. Published with Assistance of the Knapp Testimonial Fund of the Section on Ophthalmology of the American Medical Association. Denver: Herrick Book and Stationery Company, 1915.

Volume XI. of the Ophthalmic Year Book contains 545 pages of text, about 100 more than is contained in Volume X. Its contents are associated under thirty headings. This volume begins with a preface, followed by Biographic notices of oculists deceased during the year 1914. Then comes the review of ophthalmological literature, the abstracts arranged in logical order. Four hundred and forty-four pages are devoted to the review, and seventy-five pages to bibliography. There are some illustrations in black and white. The abstracts are full and very satisfactory. This is the best work of its kind in English: it reflects great credit on its editor and founder and also on his collaborators. The work deserves the liberal support of all English reading ophthalmologists.

Syphilis und Nervensystem. Neunzehn Vorlesungen für praktische Aerzte, Neurologen und Syphilidogen von Professor Dr. Max Nonne, Oberarzt am Allgemeinen Krankenhaus Hamburg-Eppendorf. Dritte, neubearbeitete Auflage. Mit 155 Abbildungen im Text. Preis Mk. 30. Berlin: Verlag von S. Karger, 1915.

The previous edition of this work, which appeared in 1909, has been enlarged by about 200 pages, which are partly accounted for by the addition of 58 illustrations. The number of chapters is naturally unchanged, but the arrangement of the subject shows marked departures which may be ascribed to recent advances in neurology. The author in his preface states that a partial rearrangement has been necessitated as a result of the thorough discussion of such subjects as the *Spirochæta pallida*, Wassermann reaction, new cytology of the cerebrospinal fluid, the luetin reaction, and last but not least, salvarsan. In other respects the former order of the book remains the same.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held November 4, 1915.

THE PRESIDENT, DR. WALTER B. JAMES, IN THE CHAIR.

Dr. Francis Delafield.—Dr. THEODORE C. JANEWAY read this appreciation. (See page 929.)

The Management of Patients with Chronic Renal Disease.—Dr. THEODORE C. JANEWAY of Baltimore presented this paper, in which he said that it had been his fortune during the development of the tests for kidney function, both at the Presbyterian Hospital in New York City and during the past year at Johns Hopkins Hospital, to have for his associates a group of men actively interested in this field. During the last year, especially, Dr. Rosenthal and Dr. Rountree and their coworkers had, by their laboratory studies, quite definitely modified their practice in the wards. He would therefore give their present views on the practical management of the different types of chronic renal disease which were commonly met in general practice. Dr. Janeway said he had used the expression "practical management," because, except in the rarest instances, they had no real treatment of the disease. The problem of fundamental importance with reference to renal disease as its causation, and except for certain cases of renal involvement in secondary syphilis, possibly rare cases of nephritis due to malaria, lead poisoning, pregnancy, or some focus of infection, they could not speak of an effective causal therapy of chronic nephritis. The treatment of chronic diseases had two aims, the prolongation of life and the amelioration of the discomforts due to the disease. These two aims were achieved by two types of treatment: (1) safeguarding treatment which aimed to protect a weakened function from further damage by overstrain, and (2) symptomatic treatment. The estimation of the kind and degree of functional damage was of fundamental importance in determining treatment along either of these lines. Dr. Janeway said that chronic renal disease presented an endless variety of symptom combinations, but certain clinical types occurred with such frequency that we were all called upon to meet the problem of their management, and as they presented, in a way, specific practical problems he would consider them as such.

1. Patients in Whom Albumin and Casts in the Urine Were the only Evidence of Disease.—This was a large group in whom the condition was frequently discovered accidentally. In this group a searching inquiry must be made into the history for evidences of a past or existing infection. If such evidence were found, especially in young people, then a period of rest in bed and milk or bland diet should be given a thorough trial. If the treatment as of a true acute nephritis resulted in a steady subsidence of the albuminuria, it should be persisted in as though the patient had a known acute nephritis. If, however, there was no suspicion of a past infection, and if a week in bed on a milk diet had no appreciable effect on the albuminuria and casts, then bed and milk diet were unwarrantable hardships. In children there must be a differentiation of postural albuminuria. This was commoner than was supposed. Testing the separate urines passed at different times a day, and the effect of standing fifteen to thirty minutes in marked lordotic position would often clear up the diagnosis. The large amount of protein precipitable by acetic acid in the cold had been, in the writer's experience, an important feature of the albuminous urine in these cases. The treatment should be along lines of general invigoration, with medical gymnastics for the improvement of the posture. Their diet should be ample, not restricted. There was a large class of patients in whom the cause of the albuminuria was not evident, and in these the effects of exercise, cold baths, and so on, upon the albuminuria should be carefully studied. These patients should be watched over long periods of time in the interest both of science and of the patient. A tendency toward nocturnal polyuria, or fixation of specific gravity were almost certain danger signs; and until such symptoms arose symptomatic treatment was quite unnecessary. Safeguarding treatment, however, was important, but must not go beyond what was of proved efficacy. Soups and spices might wisely be excluded from the diet, gourmands should have their excessive appetite restrained, and obese patients should be moderately reduced. If the phthalein test was normal the writer said he saw no reason for the restriction of the protein, either qualitatively or quantitatively, below a moderate normal intake. Those who used large amounts of salt in their food should be told to reduce it partially as training for a possible subsequent treatment of edema. For diabetics with albuminuria, unless the phthalein test showed an excretion below 40 per cent., or there were definite symptoms, such as edema, the treatment similar to the dietetic treatment of diabetes, and the albuminuria should not be allowed to interfere with this.

2. Patients with Hypertension, with or without a Trace of Albumin, and with Slight Subjective Symptoms or None at All.—The vast majority of these patients certainly had changes in the renal vessels and in the arterioles elsewhere, but the clinical type did not have renal symptoms. Slight cardiac or neurasthenic symptoms were common. Safeguarding treatment was the entire problem of their management. They should be safeguarded from all influences that raised the blood pressure in the normal man, and the myocardium and to a certain extent the cerebral vessels and the kidney should be safeguarded. The worst hypertensive influence was mental strain, and especially emotional strain. The condition called for a reasonable adjustment of the everyday life. The limitation of the diet followed much the same lines as in the preceding class of patients, but physiological economy in nutrition should be insisted upon, and meals should not be bulky. High blood pressure was no indication of nitrogen retention, as Folin, Denis, and Seymour had shown; luxus consumption clearly should be, and it was possible that some patients would be better without meat. The moderate use of tobacco or light wines would have to be regulated according to their effects on the individual patient. Climate was not without its influence, the majority of these patients having more symptoms during cold weather.

3. Patients with Hypertension and Outspoken Myocardial Insufficiency.—The writer stated that this was one of the largest groups to be found in the medical wards of every hospital, and these patients were equally common in private practice. They presented primarily the treatment of a circulatory disease. For them both safeguarding and symptomatic treatment were essential. The symptoms demanding treatment in the majority of cases were edema, dyspnea, and the whole picture of cardiac failure. For those having anginoid pain the safeguarding treatment was rest. As a vasodilator fresh nitroglycerin tablets dissolved on the tongue and not swallowed fulfilled the indications and were free from the disagreeable publicity that the breaking of an amylnitrite pearl entailed. Theobromine might be valuable in some cases. The patients with ordinary myocardial failure should be studied by the nephritic test meal of Schlayer and Hedinger, which Rosenthal had adopted in their clinic at Johns Hopkins Hospital with excellent results. There should also be a phenolsulphonephthalein test as a preliminary to treatment. If in addition the blood urea and the Ambard coefficient could be determined, very valuable information might be obtained. The phthalein output was usually low, often under 30 per cent.; if normal, or nearly so, and the test meal showed no lowering of the nitrogen concentration in the urine, and no marked nitrogen lag, then it was rarely necessary to determine the blood nitrogen. Only in moribund patients could important retention exist. It was also essential to recognize the presence or absence of fibrillation of the auricles as a guide to the use of digitalis. All these patients required rest in bed or in a chair if they were orthopneic, as the essential safeguarding treatment for the heart. Those patients without auricular fibrillation, but with marked edema and a congested liver, should also be placed on digitalis. The method of the administration of this drug must be determined by the details of the case and the habits of the physician. Toxic effects of digitalis must be watched for and heeded; if it did not succeed alone with proper diet, then one of the caffeine diuretics, theocin, about 12 grains a day, or diuretin, about 40 grains in divided doses not oftener than every other day. It was important to have the fluid intake and the urine output accurately measured, and it was helpful to have the daily weight recorded. Regulation of the diet was one of the most essential features of treatment. Their functional studies had now enabled them to base this upon the individual requirements of the case, not upon so-called general principles. The three factors to be considered were the fluid, salt, and

nitrogen intake. Practically all these patients required limitation of their fluid intake. A high Ambard or a falling index of urea excretion, or blood nitrogen above the normal, indicated the need for limitation of the protein intake. Ambard considered the normal constant 0.07. Unpublished observations by Lewis in their clinic had shown that 1.09 was more nearly the upper normal limit. There was considerable difference of opinion as to the figure for urea which might be found in the blood of healthy persons, but their experience coincided with McLean's that 50 mg. per 100 c.c. was possible with very high protein diet. Apart from this 40 mg. should never be exceeded. The urea nitrogen was practically one-half of this. The total non-protein nitrogen should not pass 50 mg. per 100 c.c. under any circumstances. The practical means of accomplishing this limitation varied from a low protein diet, which could never be an exclusive milk diet, to an introduction of short periods of nitrogen starvation in the worst cases. Failure to eliminate salt made essential the reduction of the salt intake to a figure below the twenty-four-hour output. Where much edema existed a rigorous salt-poor diet containing less than 3 grams, if possible getting the amount down to 1 gram, was most desirable at the start. In patients with myocardial insufficiency and marked edema the Karell diet was ideal. This consisted of 800 c.c. of milk in twenty-four hours as the only food or fluid allowed. When diuresis was abundant and the dropsy was disappearing rapidly the amount of milk could be increased up to 1500 c.c., and then other appropriate food gradually added. It was desirable to determine the degree of restoration of the power of the kidney to excrete salt before allowing a return to a full diet. All such patients should be warned against the abuse of salt in the future and against other dietetic indiscretions. After recovery the return to physical activity must be by very gradual stages. Tobacco should be forbidden, but he was not sure that a little alcohol was harmful. Fibrillating cases, if they showed any tendency to a rate above normal, should take small doses of digitalis more or less constantly, the dose to be determined by observation.

4. General Edema Without Notable Myocardial Insufficiency the Prominent Symptom.—This group of patients was much smaller than the preceding and was met more frequently in hospital wards than in private practice. A considerable proportion of these dropsical patients had a subacute or chronic diffuse nephritis. This was what Dr. Delafield called chronic diffuse nephritis with exudation. A number of these patients under careful treatment would eventually make a functional recovery; others developed increasing renal insufficiency with uremia, and entered the next group. To the group under consideration belonged a few patients with obstinate edema and low blood pressure, showing amyloid kidneys at autopsy; others were examples of a degenerative lesion of the tubular epithelium and the pregnancy kidney. Their diagnostic criteria were the absence of blood elements in the urine and the low blood pressure. These patients showed a striking failure to excrete salt, the salt concentration in the urine being often as low as 0.1 per cent., and the daily output not over 1 gram for long periods. With this the amount of urine was naturally small. The important point in these patients was the determination of the degree of impairment of the ability to excrete water and salt. The treatment should always begin by a period of very low salt and water intake to promote rapid absorption of the dropsical effusions. When this was accomplished the response to increased water and salt intake should be tested from time to time, and care should be exercised to keep always below the tolerated amount. It was desirable to keep the patient in bed until normal function was established. Some of these patients required accessory dehydrating measures, of which hot-air baths had been in the experience of the writer most effective. Borderline cases between this group and the preceding required a suitable combination of cardiac therapy with that just outlined.

5. Advanced Renal Insufficiency; Uremic Symptoms Superimposed Upon One of the Foregoing Types.—This would be recognized as the classical picture of the end stage of chronic Bright's disease. The differentiation of the severe headache of uremia from that due to cerebral vascular disease, or of a uremic from an organic coma or hemiplegia might be very difficult. Lumbar puncture sometimes gave the clue and should be resorted to. However, the uremia under consideration scarcely permitted of confusion, except with similar toxic states, as in the end stages of liver disease. Changes in the optic nerve or retina were practically always present in true uremia, and the functional tests showed what might well be considered as quantitative renal insufficiency. The test meal could be safely used only in the early stages, and then should frequently have its protein content reduced. It indicated inability of the kidney to excrete the normal constituents in anything but low concentrations. The functional picture was constant in advanced contracted kidney, but might vary from week to week in diffuse nephritis. In their experience both nitrogen and sodium chloride concentrations had been equally reduced. The phthalein test was of diagnostic, prognostic, and therapeutic importance. The excretion was diminished in proportion to the renal insufficiency and, as a rule, paralleled closely the Ambard coefficient and the degree of increase of the non-protein nitrogen of the blood. The Ambard coefficient was always raised and was unquestionably the most accurate measure of the degree of impairment of the urea excretion. The Widal figures remained the nearest approach to a prognostic standard, if one remembered that they were obtained by the hypobromite method, and represented more nearly total non-protein nitrogen. With 50 to 100 mg. long survival was possible, though prognosis must be guarded. With more than that quantity no case lived more than two years. No case with over 300 mg. of total non-protein nitrogen per 100 c.c. or an Ambard above 0.4, lived many weeks. The treatment of the severest cases of renal insufficiency was purely symptomatic, and not a cheerful duty. Morphine was effective, but occasionally precipitated the rapid onset of anuria with coma, and once begun had to be used in increasing doses. Chloral hydrate in 5 or 10-grain doses, alone or combined with moderate doses of bromides, was sometimes very effective. Sodium nitrite, given fifteen minutes before bedtime, was sometimes effective as a remedy for insomnia. The gastrointestinal disturbances were of central nervous origin or eliminative. Lavage of the stomach and bowels was worth trying, but for the most part the control of these symptoms was a problem in the use of general sedatives. Diet was usually reduced to a minimum by the patient, for anorexia was the rule. In the early cases a low nitrogen diet was strictly indicated, with nitrogen starvation on days of severe symptoms, giving as much carbohydrate as possible. They had had a few remarkable improvements with this treatment. Of the direct measure to reduce the retention of poisons, bleeding took the first place, and had its greatest value in the case of sudden convulsive seizures. The removal of 500 or 600 c.c. of blood was regularly indicated, and recovery was common. Sweating seemed occasionally to fit the patient. The most important treatment in uremic cases was of associated myocardial insufficiency. Of equal importance, but less generally appreciated, was the urgent necessity for the treatment of any associated obstruction of the urinary tract. Back pressure from an enlarged prostate, combined with a slightly damaged kidney, might rapidly lead to severe renal insufficiency with uremia. The possibility of improvement by nephrotomy or decapsulation in certain cases both of acute and chronic nephritis, which did not respond satisfactorily to other measures, should be seriously considered by medical men. This field was peculiarly one for cooperative study. In closing, Dr. Janeway said that in spite of modern methods, we were not one whit nearer the goal of treatment—prevention or cure of the disease, and every attempt to approach this problem from a new viewpoint should be enthusiastically welcomed by the medical man.

Dr. Nellis B. Foster said that Dr. Janeway had made clear the temerity of attempting to treat renal disease without an exhaustive study of the case. Formerly our studies were directed toward arriving at an anatomical diagnosis while now we knew they must go further, since therapy depended on function. The treatment of chronic disease was the intelligent adaptation in demand on organic weakness. At present complete knowledge of renal function was acquired only through metabolic studies which were arduous and time consuming, and it was to be hoped that in the near future new tests would be discovered by means of which necessary facts could be learned with greater facility. The functional test was a short-hand method to metabolism results. In considering the type of chronic nephritis without edema Dr. Janeway had emphasized the fixation of the specific gravity of

urine as characteristic. Even more striking was the fixation of nitrogen concentration; while with a normal kidney the nitrogen concentration might reach to 2 per cent. on demand, the sclerotic kidney might not be able to excrete a urine of as much as 0.5 per cent. of nitrogen. The elasticity of function was gone, the limitation was definite and low. When the urine output was under 2 liters per day there was frequently a nitrogen retention with these cases. They had been interested at the New York Hospital in observing during their metabolism studies on these cases the effect of copious water ingestion on the nitrogen output, and they had noted that with many cases it was possible to secure a flushing out of large amounts of accumulated nitrogen in this way, the patient being evidently improved by this therapeutic measure. Of course, a certain danger lay in the burden thrown thus upon a heart probably of weak musculature, and this must be watched. Concerning the type of nephritis with edema, he regarded a pure chloride-water retention as rare. There was usually some nitrogen deficit, though it might be slight, and required a period of observation for demonstration. It was of some interest, perhaps, that analyses of muscles and tissues from cases of what appeared to be pure chloride retention indicated a nitrogen disturbance. There was, of course, an increase of water in these tissues, but even then there was a relative and absolute increase in extractive nitrogen. Whether this had any relation to the causation of edema we did not know. This accumulation seemed not to be found with cardiac edema.

Dr. Lewis A. Conner said he would touch upon only a few of the many important points brought out in Dr. Janeway's admirable paper. Referring first to the group of patients in which the kidney disturbance was shown only by the presence of albumin and casts in the urine, and especially to the adolescent cases, his experience had been that, while some of them were clearly instances of postural or orthostatic albuminuria, in others it was difficult to say whether the condition should be regarded as only of this type, or whether there was not some grade of actual nephritis present. In either case, he wished to endorse and emphasize Dr. Janeway's warning against too rigid dieting. These growing children required an abundant, nutritious diet, including the various forms of protein, and attention should be paid to their proper growth and nutrition rather than to the local condition. In the pure hypertension cases, his experience agreed entirely with that of Dr. Janeway that measures directed toward allaying mental strain and emotional disturbance were of much more effect than were any attempts to lower the blood pressure by means of drugs or other direct methods. Much could be done by readjusting the mode of life by the insistence upon bodily and mental rest, and by reassurance and encouragement. While the introduction of the sphygmomanometer had been of the greatest value in many ways, it had brought with it its own train of evils, and one saw many patients of this class whose condition was aggravated by their constant attention to, and their worry about, their high blood pressure, and whose spirits rose and fell with each insignificant fluctuation in the mercury column. Dr. Janeway had brought out an important point, and one which most had failed to recognize, in calling attention to the fact that in the cases of grave renal insufficiency the manifestations of uremia might be precipitated by failure of cardiac compensation. Finally he said he wished to endorse his view that in conditions of cardiac insufficiency complicating renal disease, digitalis might be of great value and should be used even when no fibrillation of the auricle existed, and when the cardiac rhythm was normal.

Dr. Warfield T. Longcope said that among the many interesting points which Dr. Janeway had so ably discussed, there was one which, with Dr. Foster, he should like to emphasize. For some time they had all been impressed with the necessity of limiting the intake of chlorides, the intake of water, and the intake of nitrogenous foods in many cases of nephritis, so that one almost forgot that there were cases, namely, the nonedematous types, with high pressure and poor concentration of chlorides and nitrogenous material in the urine, in which it was perfectly rational to give large quantities of fluids. In these individuals concentration of sodium chloride usually remained constant whether the patient excreted 500 c.c. of urine or 2 liters, and consequently it was rational to suppose that with the elimination of large quantities of urine, larger amounts of sodium chloride and nitrogenous material would be excreted. In certain selected cases when the excretion of water was not materially interfered with, they had employed one of the oldest methods in the management of nephritis, and had given the patients as much as two, three, or even four liters of fluid a day. In the severer cases hot packs had been employed, together with forced fluid. It had seemed to them that many of these patients had been more comfortable under this régime than under any other which they had tried in the individual instance. In certain cases, undoubtedly, forcing fluids was harmful, but in selected cases it might be used as a true therapeutic measure.

Dr. Louis Faugeres Bishop said that the elaborate and scholarly paper of Dr. Janeway, commencing with his well-deserved eulogy of our great teacher, Dr. Francis Delafield, represented a complete study of the excretory findings in kidney disease. Just as Dr. Delafield said the final word in the morphology of nephritis, so this paper might very well represent the final word in the studies of the ultimate chemistry of nephritis. From now on Dr. Bishop said he did not think this field would be very fruitful. Dr. Janeway had asked for suggestions that might lead to the further development of these studies. It seemed to him that this must be found in the study of the whole protein molecule rather than in the study of the final elements of its destruction. The work that Dr. Janeway had given us represented a continuation of the application of inorganic chemical methods to the study of disease. Inorganic chemistry, as a rule, was satisfied with the measurement and study of elements. What we needed for the further elucidation of these diseases was, first, an appreciation that they were really diseases of metabolism and not diseases of elimination; that they must make a new beginning, starting from the broad field of biochemistry and focussing finally upon the special organs involved, rather than working back from structural change and chemical end-products to original causes. The study of proteins in the blood was bound to be a barren field since it seemed pretty evident that the tissues and not the blood were the repositories of the cruder proteins as they came from digestion and the waste products as they formed. The blood was simply the temporary carrier of protein, and the quantity found would depend upon the time of observation rather than anything else, just as amino acids were found in the blood stream only after a meal as they floated from the intestines to the tissues. There was a fruitful field in the study of acquired sub-symptomal idiosyncrasies, particularly relating to the proteins of animal origin. These seemed to him to be the basis of much cardiovascular-renal disease, and the result of dietary treatment was very brilliant. Most people suffering from cardiovascular-renal disease were sensitive to meat, many were sensitive to fish, and not a few to eggs. It was in the nature of a mild anaphylaxis, which kept all the cells of the body in a state of mild irritation, and finally led to definite organic disease. So dietetics became rather a qualitative than a quantitative matter. The exclusion of the particular protein to which the person was sensitive limited the trouble and the symptomatic improvement was extraordinary. He had elaborated this theory in a whole book, so could hardly make it clear in a brief discussion. It was a very good thing to hear Dr. Janeway recommend exercise in the management of certain persons suffering from very high blood pressure. When this idea was first proposed a few years ago, it was subjected to severe criticism, but he was sure no one who had really tried it had any doubt that outdoor exercise was one of the best remedies for these people.

SECTION ON MEDICINE.

Stated Meeting, Held October 19, 1915.

Dr. T. Stuart Hart in the Chair.

An Outbreak of Typhoid Fever and Its Cause.—Dr. S. R. Blatteis presented this paper, in which he first reviewed briefly the history of a number of epidemics of typhoid fever occurring in New York, and considered the evidence pointing to the sources of such epidemics, as worked out by the Department of Health, through its division of epidemiology. Of these sources, milk appeared by far the greatest offender, with water, flies, and carriers as other sources of infection. Water had only in rare instances been proven to be the cause of a typhoid outbreak in this city. The relative increase of milk as the cause of typhoid fever in this

city compared to water differed from the results obtained from a study of 638 epidemics in other places, of which only 17 were traced to milk and 77.4 to water. The essayist cited the recent epidemic which prevailed on Hart's Island as illustrative of a fly epidemic. A personal inspection after the development of 14 cases, following the admission of a case in the incubation period, revealed such conditions in the improvised hospital ward, where young inmates were acting as nurses, that the number of cases subsequently developing totaled 95. Here were observed myriads of flies feeding on typhoid stools, carelessly spilled over bedding and floor. Flies invaded all corners of the institution, making it difficult to see how any food products could escape contamination. After referring to the rôle of the typhoid carrier as a source of the disease, Dr. Batteis described the typhoid epidemic which occurred in the Park Slope section of Brooklyn in the fall of 1914. This epidemic was traceable to an ice-cream and confection parlor, where an individual was employed from whose feces typhoid bacilli were subsequently repeatedly isolated, but who gave a history of never having had typhoid fever, and who in spite of specific treatment still showed the specific organism as late as two weeks ago. That the largest number of cases for which no source of infection could be discovered was due to typhoid carriers there was little room for doubt. Thus recent measures adopted by the Department of Health, such as making Widal tests of all food handlers and examining the feces in suspicious cases, had for their object some possible improvement in this respect. Oysters and shellfish played a minor rôle in the epidemiology of typhoid fever. More rare than infection by oysters and shellfish were the records of infection by vegetables and fruit, and nowhere among all the records or in the literature was there reported an instance of an outbreak of typhoid fever due to the eating of watermelons. The history of such an epidemic was as follows: On July 12, 1915, a group of children, eight or ten in number, all from one block near the Upper Narrows of New York Bay, went to the beach and noticed a large number of watermelons in the water. All the melons were either damaged along one end or split along the body, and the portion near the damaged end could not be eaten because of its salty taste. The children carried home what they could and distributed pieces to other members of the family. In from one to three days after the ingestion of the melon the children and a few adults, who had eaten of the melons, with but few exceptions, suffered from an acute attack of gastroenteritis, characterized by nausea, vomiting, severe abdominal cramps, diarrhea, and, in some instances, marked prostration. They all recovered, and, after a perfectly well interval, some of the children became ill. On July 24, twelve days after the melon party, appeared what was reported to be the first case of typhoid fever in a child eight years of age. Then in rapid succession 12 cases developed within about two weeks. No secondary cases developed. The clinical data in these cases did not differ from the average type of the disease. The evidence that this outbreak had its source in the watermelons was based upon (1) the period of incubation, which averaged eighteen days (the average given in the literature of a large series of cases); (2) the Widal test, which was requested in only five cases, three being positive, one doubtful, and one negative; (3) the Diazo reaction, positive in all seven cases examined; (4) examination of feces, done in eight cases, in fivt of which two examinations were made, with the result that typhoid bacilli were found; in three cases in which only a single examination was made the bacillus was isolated in one instance; (5) the duration of the disease, 25 7/10 days, which agrees with the average of 500 cases in which the duration was 29 days. Investigation of the milk and water supply gave absolutely negative results, and a detailed investigation by the Bureau of Food Inspection failed to produce any evidence in the food supply of that immediate vicinity that could be interpreted as a possible cause. The conclusive evidence pointed to the watermelons as containing the organism of this disease. The melons were picked up in the upper bay, immediately above the Narrows, where within a mile of each other two large sewers emptied, one of them draining the Bay Ridge section of Brooklyn, where at the time an epidemic of 100 cases of typhoid fever was raging.

Dr. Haven Emerson said he thought the chain of evidence pointing to the melons as the source of infection in these twelve cases of typhoid fever was perfect with the exception of the fact that a bacteriological examination of the melons had not been made. The Department of Health had for some time been studying the problems that presented themselves in connection with bathing in the waters of New York Bay. They had made bacterial examination of specimens of water taken at various points in the vicinity of the city and found the number of bacteria per cubic centimeter of water varied greatly. As bathing was a recreation that meant a great deal to the inhabitants of the city the Department of Health had been trying to work out some plan by which the waters about the city might be kept pure and they had presented the subject to the Academy of Medicine with the hope that some of the members might become interested in the matter and help them in devising some such plan. After such an epidemic as had occurred from eating the melons taken from the water the only safe course at present seemed to be that of closing all the public bathing houses along Gravesend Bay.

Dr. Alfred Meyer expressed the opinion that when it came to a question of revoking the licenses and closing the bathing houses, the argument based on the outbreak of typhoid fever caused by eating watermelons taken from the water would have to be eliminated. The bathing masters might contend that bathers did not eat food taken from the water as a rule, and they might defy the authorities to give a single instance in which bathing in the water had resulted in infection with typhoid fever. There were instances of conjunctivitis acquired while bathing in the waters about the city, but he knew of no instance in which typhoid fever had been acquired in this way.

The Use of the Roentgen Ray in Nonmalignant Conditions.—Dr. James A. Corscaden presented this paper in which he described the Roentgen ray and compared it with other therapeutic agents. He said that the Roentgen ray was different from other agents in that it might reach any part of the body or any part of the cell without being restricted in its action by the laws of fluids and osmosis. It reached the nucleus of the cell with no regard to cytoplasm and could, therefore, if the nucleus had a high power of absorption, affect this independently. The effect of small doses of the Roentgen ray upon the nucleus was to increase the cytolytic growth activity with more rapid mitosis and increase in the number of cells. In large doses this lawful activity became lawless and resulted in pyknosis and nuclear disintegration, and later vacuolization and rupture of the cytoplasm, ending in the death of the cell. The types of cells affected were those whose nuclear construction was least stable. Why, otherwise, one cell should be affected and another not, had yet to be definitely shown, but might lie in the fact that elements of different coefficients of absorption might require rays of special penetration quality for that absorption, and that this difference between cells might depend on the amount of those various substances contained in the cell. Applying this action to the tissues their susceptibility was found to be in about the following order: The lymphocytes, whether in the lymphoid structure, such as nodes, spleen, bone marrow, or blood, the thymus gland, the follicular apparatus of the ovary, white blood cells, such as myelocytes, polymorphonuclears, parenchymatous glandular structures, connective tissue, and bacteria. Myelocytes were readily destroyed, but myeloblasts were very resistant, persisting in the blood of leukemics in spite of all Roentgen ray treatment. The action of the Roentgen ray on bacteria had varied greatly, according to different observers. Basing his study on this varied susceptibility of the different tissues the writer has studied diseases of the lymphatic and blood system, the thymus gland, Graves' disease, chronic inflammation, particularly tuberculosis of the bone and lymph glands, with or without sinus formation, metrorrhagia, polycythemia, Banti's disease, Mikulicz's disease, and hypophyseal disorders. He had found that in diseases of the lymphatic and blood system the Roentgen ray was a valuable palliative agent, relieving symptoms and prolonging a comfortable existence, but was rarely curative. The immediate effect on the symptoms was an improvement in the anemia, the weight and strength are rapidly recovered, and the hemorrhages ceased, but the normal anatomical or clinical appearance was practically never reached and in the leukemias there were always present in the blood picture some, if only a few, of the abnormal white cells. However, the course of the disease might be prolonged from nothing up to three or four years. Cases with blood

changes of less than one year's duration did better than those of long standing. The prognosis was better in older persons, although they responded less to the treatment than the youthful. Hodgkin's disease derived the greatest benefit from the surgical removal of the gland, followed by radiation. Enlargement of the thymus gland could be so quickly diminished by the Roentgen ray that thymic asthma might be relieved in twelve hours. In Graves' disease, functional cures occurred in 25 per cent. of the cases treated either by attempting to destroy the thyroid gland or by destroying the thymus; some cures had persisted up to six years. In chronic inflammation, clinical cures, that was, disappearance of tuberculous lymph node enlargement and closure of sinuses, occurred in 66 per cent. of the cases treated in this way. Whether this was due to destruction of the invading organism, to increased lymphocytosis, or to stimulation of other resisting agents, was still *sub judice*. Bleeding from the uterus caused by disturbances of the factors governing menstruation or by fibromyomas causing passive congestion, but not pedunculated or ulcerated, could be permanently stopped. This result was obtained in women over thirty-eight years of age; in women under that age partial amenorrhea might be established where there was no new growth of the uterus. Fibromyomata in young women should be excised unless operation was contraindicated, when, if bleeding, they should be treated by the Roentgen ray. The speaker presented a number of patients, illustrating some of the conditions considered in his paper, who had been greatly improved by the application of Roentgen-ray therapy.

Dr. E. W. CALDWELL said that Dr. Corscaden's paper had given an excellent review of the literature and left nothing to be said as to what had been done in the *x*-ray treatment of non-malignant conditions. But in his experiments as to the physiological effects of the *x*-ray he had been struck with the fact that the data as to dosage and the application were not as plain as he would like to have them. For instance, taking white light for comparison they knew that it was composed of all the colors of the spectrum and that each color had a different wave length; likewise in the *x*-ray there was a difference. They knew that the chemical effect and the physiological effect of the violet and red rays were very different, and when they used them all together they did not know which ones were responsible for a certain effect when they got it. They knew that in the body certain tissue elements had a higher absorptive power for the *x*-ray than others. They also knew that iodine and phosphorus were more absorptive than hydrogen, nitrogen, and oxygen. Hence if they knew the chemistry of a particular tissue they could get more startling effects from the use of the *x*-ray than they did now. Again another difficulty was that of obtaining a deep effect without getting too much superficial effect; a selective action would be better. One knew, for example, that red light passed readily through a very thick piece of red glass and that it was absorbed almost completely by a thin sheet of green glass, therefore if one knew the absorption characteristic of different tissue cells better results might be obtained. Another difficulty lay in measuring the intensity, whether a given amount of radiation takes place in a shorter or longer time. Suppose that one assumed that a physical effect was produced by a certain amount of radiation in a short time and the same amount was applied over a long time, the question arose whether the same result would be obtained. These were a few of the many problems that remained to be worked out. There was a great deal still to be done and until some of these problems were solved they did not know what would or could not be accomplished by the *x*-ray.

A Case of Hydro- or Pyo-Pneumopericardium Complicating a Spontaneous Pneumothorax. — Dr. ALFRED MEYER presented this communication (see page 991).

Dr. MAX TASCHMAN said that this patient had first come under his observation in the tuberculosis clinic of the Mount Sinai Hospital and was found so ill that only a hurried examination was made, and he was immediately transferred to Dr. Meyer's hospital service. The clinical picture presented by this patient was interesting. The patient appeared gravely ill, his face was pinched, clammy, and cyanosed, like that seen in severe cases of pneumonia just about the time of crisis. The cyanosis was so extreme that but for the rapid breathing it might have suggested argyrosis. The breathing was labored, shallow, and painful. His pulse was rapid, thready, and irregular. Examination of the chest revealed the usual signs of infiltration, involving the upper half of the right lung front and back and the upper part of the left upper lobe. Over the greater part of the left lung, posteriorly, the percussion note was hyperresonant, the respiratory murmur diminished, and almost absent at the base, with metallic fremitus. The condition of pneumothorax was at once recognized. Pleural effusion was sought for, but was not found. These signs were likewise evident anteriorly, but less marked. While auscultating the left chest behind, the speaker said he was struck with a physical phenomenon that he had never before encountered. This was a loud, metallic, splashing, churning sound, synchronous with the heart beat and of appreciable duration. It was heard louder behind than in front and much more distinctly with the unaided ear applied to the chest wall than with the stethoscope. It was evident that they were dealing with a cavity containing air and fluid and lying close to the heart. A diagnosis was therefore made of left-sided pneumothorax with a secondary cavity in the lung containing fluid adjacent to the heart. An *x*-ray examination clearly demonstrated that this secondary cavity containing air and fluid was situated within the precordium. McPhedran, in his article on pneumopericardium with effusion, in Osler's "System of Medicine," stated that the diagnosis of this condition must be differentiated from pneumothorax on the one hand, and, on the other, from a large pulmonary cavity with fluid lying adjacent to the heart. Within the past few years he had had the opportunity of studying a fairly large number of cases of induced pneumothorax, and in no case were the heart sounds audible over the area of pneumothorax behind. In those cases complicated by pleural effusion the same held true. It was conceivable that where an extensive pleuro-pericardial-epicardial adhesion existed that the heart's contraction might be communicated to the fluid in a case of left-sided hydropneumothorax. Moreover, the opportunity for this physical sign presented itself in the fairly frequent condition of precordial or pericardial cavity in instances of pulmonary tuberculosis, but neither in these cases nor in those of bronchiectatic cavity, situated above or to the left of the heart, even with marked pulling over the heart into the axilla, had he ever been able to elicit the metallic churning sound so clearly evident in the case presented by Dr. Meyer. This sign, heard loudest with the unaided ear, was almost pathognomonic of this pneumopericardium with effusion. The *x*-ray was of great value in the study of this condition.

Dr. HENRY WESSLER said that he had studied this case with Dr. Meyer and had nothing to add, though he might emphasize the point that the linear shadow might be due to displacement of the mediastinum. It was possible that the mediastinal shadow might produce an effect like this, but by placing the patient in various positions, if there was air in the pericardium, one would get the shadow in all positions. The lateral and dorsal positions would show the linear shadow and the heart could be seen surrounded by air in front and on both sides, and this made the significance of this particular shadow fairly certain.

Dr. MAURICE FISHBERG stated that the case reported by Dr. Meyer was very interesting, but he believed that pneumopericardium, while an uncommon condition, was not as rare as would be expected considering that it was so rarely mentioned in medical literature. Still, in Leube's textbook on diagnosis there was given a rather complete description of the etiology and symptomatology of the disease. He had met with several cases of a splashing sound synchronous with the cardiac systole. The last one he detailed and presented *x*-ray plates showing a hydropneumothorax, though there was no air visible within the pericardial sac. In his case the splashing systolic sound was preceded by pleuropericardial friction sounds for two days. After lasting for about three days, the plashing sound disappeared but then a metallic tinkle was audible, as was frequently the case in hydropneumothorax. The patient made a good recovery, as regards the pneumopericadium; the pneumothorax was absorbed and the underlying phthisical process went on its course.

Dr. L. T. LE WALD stated that he had slides of three cases of spontaneous pneumothorax on the left side, which he would like to show. Two of these cases made a complete recovery and the other was still under observation. These were instances of spontaneous pneumothorax *without tuberculosis*. The first case was

that of a man 25 years of age who suddenly felt something give way while taking a shower bath. Roentgen examination showed left-sided pneumothorax. After the patient had been put on proper exercise (blowing in bottle, etc.) for two weeks a second radiograph was taken, which showed complete disappearance of the pneumothorax. There had been no evidence of recurrence. The second case occurred in an errand boy 16 years of age, and was due to a slight traumatism. He was knocked down in the street, became unconscious for a short time and developed the pneumothorax involving the left side. The air was aspirated and after two weeks he had recovered full lung expansion. The third case, occurring in a boy 12 years of age, was also a spontaneous left-side pneumothorax. All of these three cases were on the left side and Dr. Meyer's case was on the left side, making it seem that there was a predilection for the left side in this condition. In this boy the heart was displaced toward the right side. He did not go through so favorable a course as did the two previous cases, but at the end of one month still had the displaced heart, and at the end of six months his condition was about the same as before.

Dr. Alfred Meyer, in closing the discussion, said that Dr. Fishberg's case had impressed him as one in which there might be pericardial adhesions which would give a peculiar splash during systole and might lead one to believe that the peculiar splash to which he had referred was present. As to the splash that occurred with hydropneumothorax, whether spontaneous or the result of the injection of nitrogen, they had made every attempt to check it up with other conditions, but they could not get this characteristic splash nor could they get positive proof that others got it. If one thought that he might be dealing with a case of hydropneumothorax he should determine whether he got the peculiar splash in all positions of the patient and then having heard it he should get a radiograph to see whether it was not a heart pumping through air and fluid in the pericardium, this condition complicating hydro-pneumothorax.

COLLEGE OF PHYSICIANS OF PHILADELPHIA

Stated Meeting, Wednesday, November 3, 1915.

The President, Dr. James C. Wilson, in the Chair

Some Physical Facts About the Radioactive Elements as Applied in Medicine.—Dr. William S. Newcomet called attention to some of the more common misconceptions of the radioactive elements and emphasized the desirability of establishing centralizing an institution where radium, thorium or other such agent might be obtained in desired amount and therapeutic activity. He believed that the usefulness of radium would be impaired just so long as it remained in the hands of private institutions, or worse still, in private hands. Radium and its allied elements were divided into two groups: (1) For the purpose of irradiation; (2) for the employment as medicine internally. In its local use the principal and most penetrating ray of radium was the *x*-ray, analogous to the Roentgen ray. A second ray known as the beta ray was analogous to the cathode ray; a third, the alpha ray, was said to be practically worthless in external applications, although 90 per cent. of the energy of the radioactive elements was of this form. It was to be remembered that radium was merely the parent and gave forth the elements which gave rise to the "active deposit." While the rays of thorium were still more penetrating than those of radium its use was necessarily confined to the applicator method and its manipulation from a chemical standpoint was difficult. An instance demonstrating the need of laboratories supplying these preparations and accurate measurement was that of a reputable dealer who had for sale two tubes of radium which he stated had been purchased from a well known chemical house, the price having been $400 and $1,400. The actual value of the radium had been found to be 40 cents and $30. Attention was called to the confusion between the so-called rays emanating from the different radium elements, and the emanation which was an element and a gas, subject to all the laws of other gases, and which when confined within a tube could not escape. It was pointed out that in the internal administration of radium or of thorium, it was the radioactivity and not the elementary base which affected the system. Radium might be given as a salt, soluble or insoluble; or, it might enter the system as a gas in the form of an emanation. The salts gave off the emanation in proportion to their age, continuously and in a definite ratio as long as they were contained in the system. It was to be remembered that insoluble salts allowed only about 2 per cent. of the emanation to escape. Radium might be obtained in solution and its strength and dosage estimated. The exact effect of the sulphates of the body upon it was said to be not definitely known. While in the body it gave forth its activity, changing slowly into the emanation, the emanation in turn to the "active product." Should an insoluble salt be administered it passed along the alimentary canal unabsorbed but gave off the emanation and active product which were absorbed. The major portion of this emanation, however, it was said, remained occluded within the intermolecular spaces of the insoluble powder and its effects continued until it was eliminated. Although given in solution water containing emanation should be used at its source. When this was not possible the commercial emanation, though not very efficient, should be used under the best conditions. The desirable product for the internal administration of thorium, it was said, was thorium X, and this had about the same period of life as radium emanation. Since it was a salt instead of a gas it remained within the system undergoing a very rapid change to emanation and "active product" and was, therefore, more powerful than the radium product. Although the therapeutic value of these extremely powerful agents had by no means been yet established, they were being employed by persons with little comprehension of their effects. While beyond doubt they were of value the results obtained were in proportion to the skill with which they were administered.

Dr. Solomon Solis-Cohen said that in estimating the value of any method of treatment which was to a certain extent new or unfamiliar certain difficulties arising were: (1) from the extravagant statements of those who used the treatment without much thought of what was to be expected and without much ability to criticise results; (2) from the skepticism of those who had made no use of the method but denied its value *a priori*. The greatest difficulty of all, however, he thought arose from its use, even by intelligent persons, with extravagant expectations of what was to be accomplished. Failing to realize such expectations, the method was condemned as valueless. Personally Dr. Cohen had seen no convincing explanation of the therapeutic effect of radium emanation water, yet it was known that in some pathological conditions, certain definite changes might reasonably be expected to follow, although not in every case. In his early experience with radium emanation water in a few cases of arteriosclerosis and in a few cases of high tension from other causes in which it was used, a marked lowering of blood pressure had been observed. In other cases exactly similar in every respect, so far as he could observe, this effect had not been produced. He had found three forms of radium emanation apparatus trustworthy. In selected cases of a limited number of affections, chiefly of the joints, and of certain metabolic aberrations, he stated that with this agent reasonably good results were obtained in an uncertain proportion of cases,—and in his opinion that was all that could be expected. In one case of long-standing osteoarthritis of the spinal column and in a number of cases of arthritis deformans of the extremities he had seen better palliative results by this methd of treatment than he knew how to obtain by other means; also in a number of gouty patients there had been considerable amelioration. He had seen no case of arthritis deformans or of any other chronic affection of the joints, or gout, or chronic metabolic disturbance cured by means of radium emanation. It was to be remembered that radium emanation was an agent of limited power which was to be used with discretion and intelligent appreciation of the laws underlying its action.

Dr. A. B. Hirsh asked Dr. Newcomet's opinion of the intravenous injection of radium.

Dr. Newcomet, in closing, said he had not attempted to speak upon the physics of radium and called to mind the presentation of a paper before the College a year ago by Dr. Goodspeed in which the different methods of measurement were given. His aim had been to call attention to common mistakes in the use of radium and especially to emphasize the desirability of establishing a central station for supply that every physician might obtain radium, thorium, or other agent, in desired amounts and possessing therapeutic activity. Reply-

ing to Dr. Hirsh, Dr. Newcomet said that he had mentioned in his paper the soluble and insoluble salts of radium and also the gas—the emanation; it should be remembered that radium sulphate was the most insoluble salt known; just what effect the sulphur of the human economy would have upon radium was still unknown.

The Occurrence of Miliary Tuberculosis of the Liver in the Course of Pulmonary Tuberculosis.—Dr. ROBERT G. TORREY presented this paper, which was based upon a study of the reports of 132 autopsies upon subjects showing pulmonary tuberculosis. The frequency with which an apparently recent and widespread miliary tuberculosis of the liver was found at autopsy in cases of pulmonary tuberculosis, and the finding that in cases of phthisis dying from other causes, as fatal hemorrhage, acute peritonitis, septicæmia, lobar pneumonia, etc., miliary tuberculosis of the liver was not found, made it appear that the hepatic involvement might be an important factor in determining the fatal issue. The author thought it probable that infection of the liver frequently took place by way of the spleen, where the tubercles were of varying age, and lie in close relation to large blood spaces directly connected with the portal vein.

Dr. WILLIAM M. L. COPLIN recalled two cases with unusual features. One was that of a girl of 14 who at operation showed extensive miliary tuberculosis of the peritoneum with voluminous ascites. The serosa was studded with gray tubercles. Nodules were present, which macroscopically appeared to be composed of tubercles within the liver. Upon excision of a fragment intrahepatic tubercles and contained bacilli were demonstrated. The patient recovered from the tuberculous peritonitis and from the lesion in the liver and has married and borne children. In the other case the liver contained tubercles clearly of different ages; one group had apparently developed shortly before death. Dr. Coplin had not found the so-called sub-miliary tubercle of the French writers so frequently as it was said to occur. Of special interest he felt was the relation of lipoids to immunity, especially to the immunity of tuberculosis. He thought it possible that in certain extremely fatty livers frequently found in patients in whom all conditions appeared favorable to the development of hepatic tuberculosis, the liver escaped because of the intracellular lipoids. He did not recall an instance of intense miliary tuberculosis in a very fatty liver.

Creeping Eruption of the Skin, with Histological Examination and the Demonstration of the Burrows and the Larvæ in the Epidermis.—Dr. FRANK CROZER KNOWLES gave a short review of the general subject of creeping eruption, referring to the fact that the histological examination had been successful in but three cases, including the one reported in the paper. The paper was based upon the study during the last three years of 3,000 serial sections from the present case. Quite a number of stains had been employed in order to bring out the various salient features of the eruption. The investigation had been most successful in that fully 150 sections showed excellent views of the burrows and thirty presented various portions of the larvæ. The present instance was the first in which the larvæ causing creeping eruption had been found in sections and also the first time that a successful histological examination had been made in America. The paper was illustrated by lantern slides in which three clinical pictures of the case were shown, four illustrations of the burrows, three drawings of the larvæ in sections, and a photograph of magnified skin showing the clinical appearance of the burrows. In comparison photographs were exhibited of the burrow caused by the mite itch, the acarus scabei and ovæ in sections, the burrows of creeping eruption from the case of Rille's and Riece's, and Sokolow's drawing of the larva. A notable fact was that while the burrow of scabies is found in the middle and upper horny layer, that produced by the larva in creeping eruption was found in the lower horny layer at the junction with the rete and also in the upper portion of the latter epidemic layer. Some of the burrows were without contents, but the majority were either partially or entirely filled with granular debris, degenerated epithelial cells, free nuclei, eosinophiles, polymorphonuclear cells, and lymphocytes. A complete histological examination had been carried out in reference to all the various layers and structures of the skin. The classification, incubation period, and mode of infection of the individual by the larva were also discussed.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

BLOOD PRESSURE WITH SPECIAL REFERENCE TO THE DIASTOLIC.*

BY LEWIS F. MACKENZIE, M.D.,

NEWARK, N. J.

ASSISTANT MEDICAL DIRECTOR, PRUDENTIAL INSURANCE COMPANY OF AMERICA.

BLOOD-PRESSURE from the systolic standpoint has been so thoroughly investigated and its normal averages at the different ages so well established, that owing to the brief time at my disposal, little attention will be paid to it.

An analysis of 18,637 records from our approved male cases during the years 1912 to 1914, inclusive, gives the systolic pressures by quinquennial periods, as shown in Table I.

TABLE I

Age Periods	Cases	Mm. Hg.	Average Systolic Pressure
15–19	187	22,316	119
20–24	1,690	205,695	122
25–29	3,351	412,908	123
30–34	4,011	498,924	124
35–39	3,934	494,350	126
40–44	2,883	367,343	127
45–49	1,550	199,992	129
50–54	677	89,254	132
55–59	257	34,697	135
60–64	76	10,411	137
65–66	21	2,917	139
All ages.	18,637	2,338,807	125

The large number of cases involved and the close agreement between these pressures and those of the Northwestern Mutual and the Mutual Benefit as reported by Dr. Fisher[1] and Dr. Van Wagenen[2] makes the correctness of the pressures at the various ages seem very certain as they practically represent a total of 36,104 cases. At no age group is there a variation of more than 3 mm. among the different records.

The limits within which this pressure may vary, under normal conditions, seem to be almost as thoroughly established (Table II) for 9,370 records in 1912 and 1913, and 9,268 in 1914, each gave a variation for all ages of 15 mm. Hg. above and 15 mm. Hg. below the average. It will be noticed that the range is a trifle smaller at the younger ages.

TABLE II—NORMAL SYSTOLIC RANGE

Ages	No. of Cases (1912-13)	Range	No. of Cases (1914)	Range
15–39	6,416	28	6,758	28
40–66	2,954	30	2,510	30
15–66	9,370	30	9,268	30

*Read at the 26th Annual Meeting of the Association of Life Insurance Medical Directors of America, Oct. 15, 1915.

SELECTED EXAMINERS

Ages	No. of Cases (1914)	Range
15–39	1,043	28
40–66	415	36
15–66	1,458	30

Dr. Fisher[1] evidently agrees with 15 mm. above as he states that, "We take our average for the age and where the blood pressure is 15 mm. in excess of that average we call that a high blood pressure, and we call for additional tests." It seems quite as reasonable to suppose that 15 mm. below is equally as accurate. This is also demonstrated by Table II, and attention is called to the fact that the range in the two groups, 1912-13 and 1914 was exactly the same.

We wish to emphasize the fact that from ages 15 to 66 there is a gradual increase in the average systolic pressure and the limits within which it may be considered normal, as shown by Table III, at no point, even in the young ages, fall below 104 mm. or at the older ages rise above 150 mm. It is felt, however, that a pressure somewhat below the low limits is not usually as serious an impairment as one equally above the high limits.

TABLE III—NORMAL LIMITS OF SYSTOLIC PRESSURE

Ages	Low - 15 mm.	Average Mm. H.	High +15 mm.
15–19	104	119	134
20–24	107	122	137
25–29	108	123	138
30–34	109	124	139
35–39	111	126	141
40–44	112	127	142
45–49	114	129	144
50–54	117	132	147
55–59	120	135	150
60–64	122	137	152
65–66	124	139	154

An attempt has been made to determine the effect of pulse rate on systolic pressure—Table IV indicates, where there are enough cases to be of any value, that for each increase of five pulse beats, the pressure rises 1 mm.

TABLE IV—SYSTOLIC PRESSURE BY PULSE RATE IN NORMAL WEIGHTS

ALL AGES

Pulse Rate	Cases	Systolic Pressure
50–54	9	124
55–59	18	117
60–64	202	122
65–69	591	124
70–74	3,783	124
75–79	2,293	125
80–84	1,184	126
85–90	224	127
50–90	8,304	125

Table V shows where there are enough cases to be of any value that there is a slight rise in pressure in the overweights; the underweights give no indication as to the effect on pressure owing to the small number of cases.

Table V—Systolic Pressure by Weight

Weight	Cases	Mm. Hg.	Pressure
30% under	8	1,030	129
20–29% under	312	38,931	125
Normal	16,738	2,095,921	125
20–29% over	1,225	157,280	128
30–39% over	313	40,472	129
40% over	41	5,173	126
Total	18,637	2,338,807	125

In Table VI the effect of height is shown. As the difference between those 5 ft. 6 in. and under and those 5 ft. 7 in. and over is but 1 mm. the effect of height is practically nil.

Table VI—Systolic Pressure by Height

Height	Cases	Mm. Hg.	Pressure
5 ft. 2 in. and under	171	21,420	125
5 ft. 3 in. to 5 ft. 6 in.	3,718	464,454	125
5 ft. 7 in. to 5 ft. 10 in.	10,858	1,262,787	126
5 ft. 11 in. and over	3,890	490,146	126
Total	18,637	2,338,807	125

DIASTOLIC PRESSURE.

In 1876, Marey devised an instrument for measuring the diastolic pressure and propounded the theory that the maximal oscillation occurred when the external pressure exactly equaled the intra-arterial and this maximal oscillation corresponded to the diastolic pressure. In 1897, Hill and Barnard invented a spring instrument for the measurement of this pressure. As the methods for reading these pressures were dependent on maximal oscillation and palpation, the results were not satisfactory.

It was not until 1905 that it was possible to take the diastolic pressure, for clinical purposes, with any degree of accuracy. In this year Korotkow announced the auscultatory method. Since then more attention has been paid to this pressure, but it is only within the last three years that it has received anything like general consideration.

The point at which to take this pressure has caused much discussion. Korotkow[4] said it should be taken at the "end tone" or beginning of the fourth phase, while Ettinger[4] believed it occurred at the beginning of the fifth phase or disappearance of all sound. Erlanger[4], in 1910, after considerable experimental work, stated it should be read at the point where the maximal oscillation became smaller, and Warfield[4], after a series of experiments, believed it occurred at the change from the clear to the dull tone or beginning of the fourth phase. Hooker and Southworth[4], on the other hand, agree with Ettinger, that it should be read at the fifth phase. Most observers now support Korotkow, in his original contention. For practical purposes, in the vast majority of cases, the difference between these two phases is so small as to be of no material significance as there is a difference between them, in normal cases, of from but 2 to 8 mm. In young subjects the difference is apt to be greater than in those advanced in age.

In spite of the fact that diastolic pressure has been so long neglected and is at the present time but slightly considered by many able clinicians, it is felt by the writer that this is the fundamental pressure upon which to base our interpretation of blood pressure readings and for the following reasons:

1. Systolic pressure is the expression in mm. Hg. of the intraventricular pressure and is subject to wide variations from physiological causes. That its variations may be great and indicate hypertension when such does not exist has been frequently demonstrated in our office.

2. Being intermittent it is less liable to produce pathological changes in the heart and arteries than is the constantly high diastolic pressure, although if long continued it, of course, has a very marked effect.

3. The diastolic pressure or peripheral resistance, is much less influenced by emotion, etc., and therefore a more accurate guide where but one or two readings are obtainable.

4. It is constant and consequently more effective in causing changes, especially in the arteries.

5. It is the constant resistance which the heart has to overcome before it can drive the blood forward, and is, therefore, the fundamental pressure as it represents:

A—The constant pressure to which the arteries are subjected.

B—The pressure which the heart has first of all to overcome.

C—The constant strain which has to be borne by the aorta and aortic valves.

It is evident, therefore, that without knowledge of this pressure it is impossible to estimate the pulse pressure, or understand the real significance of the systolic.

PULSE PRESSURE.

The pulse pressure is the expression in mm. Hg. of the head pressure or force of the heart after the diastolic pressure has been overcome. It may be entirely normal while the diastolic and systolic pressures indicate severe circulatory disturbance. It is useful only in showing whether or not the circulation is being properly maintained. The limits of this pressure have been variously estimated, as follows: Hirschfelder, 30-45; Faught, 25-40; Nicholson, 25-40; Janeway, 25-40; Erlanger, 30-40; Barach and Marks, 20-70; Warfield, 30-50; Jackson, 25-40.

Warfield[6] says: "The diastolic has been estimated to be about 45-48 mm. Hg. lower than the systolic, and consequently these figures represent the pulse pressure."

Weysse and Lutz[7] state the average pulse pressure is 35 mm.

Barach and Marks[8] have given figures which appear to be in excess of the normal range and it is felt that any pulse pressure below 25 or above 60 mm. should call for further investigation, provided we are certain as to the competency of our examiner to take the reading.

Melvin and Murray[9] regard the normal readings for the various pressures in young subjects as follows:

Systolic	Diastolic	Pulse Pressure
111.8	65.7	46

and give the range of the pulse pressure as 22-73 and of the diastolic pressure as 50-82.

Returning to the diastolic, the quotations below serve to justify the opinion previously expressed that it is the most important pressure with which we have to deal in our work.

Weysse and Lutz[7] state: "The minimum (diastolic) blood pressure is very uniform throughout the day and is little affected by the ingestion and digestion of meals . . . the average minimum blood pressure for healthy young men in the neighborhood of 20 years of age is 85 mm. Hg."

MacWilliam and Melvin[10] state: "The importance of estimating the minimal or diastolic pressure is now becoming more generally recognized and with the easy applicability of the auditory method there is no difficulty in the way of its routine use."

"As long as the diastolic pressure remains low even with very high systolic readings, the tendency to the giving way of the vessels (cerebral hemorrhage, etc.) seems to be relatively slight."

P. Ballard[11] states: "In estimating the blood pressure, the minimal pressure is much more instructive than the maximal, as Pachon reported in 1913, urging that the minimal arterial pressure be accepted as the standard for comparison."

"The maximal pressure may vary within a wide range, but the minimal pressure of 5 cm. Hg. or 50 mm. seems to be the lowest at which the blood is able to keep circulating."

Martin[12]: "The diastolic pressure appears to be more stable than the systolic and has less often shown any deviation from the normal without pathological cause. The systolic appears to accommodate itself to the diastolic more readily than the latter to the former."

Janeway[13]: "I should like to lay stress on the importance of the simultaneous measurement of systolic and diastolic pressure in determining normal conditions. (The difference between the two is ordinarily 25 to 40 mm., in my experience the lower figures being more common in women—in old men, 50 mm. may be found)."

" . . . A pulse which shows less than 20 mm. difference between systole and diastole, I think is abnormally small and over 50 mm. similarly large."

Nicholson[14] says:: "Second, the importance of routinely taking the diastolic pressure as well as the systolic as the pulse pressure . . . is often invaluable in determining the amount of arteriosclerosis present."

Nicholson[15]: "I wish to emphasize the fact that blood pressure observations should not consist of systolic pressure alone, such readings tell less than half the true situation. It is essential to determine the diastolic pressure. . . . The whole significance of the blood pressure depends on the taking of systolic, diastolic, and pulse pressures."

Barach and Marks[8] make the following comment: "As time goes on and our observations accumulate and are being interpreted, we believe that more importance will be attached to the height of the minimal pressure (diastolic) and that the height of the maximal (systolic) pressure will be considered of lesser clinical importance than heretofore. Certainly the maximal (systolic) pressure alone is of no value except as a starting point for a guess as to the activity of the circulatory system."

Warfield[16] says: "Moreover, the conviction is growing that it is the height of diastolic (minimal) pressure rather than that of the systolic pressure that is really the vital point in blood pressure determination."

Halls Dally[17] says: "Hence, the maximal and minimal pressures between which arterial pressure normally varies are the important criteria which in every case we must definitely determine. . . . To record the maximal pressure, while despising the minimum, not only affords no indication of what the mean pressure is likly to be, but resembles attempting to solve a complicated problem of which one factor only is given. . . . Now that we are in a position to institute a comparison between the maximal and minimal pressures it will probably be found that of the two the diastolic is the more important."

The above quotations clearly indicate the recognition that is now being given to the importance of the diastolic pressure. The fact is, the systolic by itself gives very imperfect information. A high systolic pressure may exist for several weeks as a result of some temporary condition which would disturb the diastolic to a much less extent, or it may be normal with serious disease and therefore taken by itself be misleading.

There is no desire to minimize the value of the systolic pressure, for when continuously high it is always a warning. That this is true has been shown most clearly by Dr. Fisher[1], and each addition made to his original report demonstrates this fact more and more.

To establish the normal diastolic pressure with its normal variations and range is far from being easy, as there are few statistics covering these points.

Barach and Marks[8], after a very interesting series of observations on young adults, arrived at the following conclusions: "The maximal blood pressure, systolic, is under 150 mm. Diastolic was found to be as follows: In 96 per cent. of a series of 338 cases at the fifth phase it did not exceed 100 mm. In 87 per cent. of a series of 312 cases at the fourth phase it did not exceed 100 mm., and reexamination of the remaining 13 per cent. of the 312 cases showed a minimal pressure not over 100 mm. In 96 per cent. of the total 650 cases the diastolic did not exceed 100 mm., at the first examination."

Nicholson[15] says: "The diastolic pressure is between 60 and 105 in healthy individuals." . . . "Even if the systolic pressure were below 150 mm. Hg. a diastolic pressure above 105 mm. Hg. would be a sure indication of hypertension, regardless of the age of the patient."

Norris[18] says: "The diastolic pressure, constantly above 100 mm. Hg. is definitely pathological at any age. The height of the diastolic pressure is often more important than that of the systolic tension. . . . A constant diastolic pressure of or above 100 mm. indicates hypertension regardless of whether the systolic pressure be 180 or 140 mm."

Again: "Given a patient with a well-marked hypertension, 190 mm. systolic, 110 diastolic, we are *de facto* warranted in assuming that the patient is suffering from Bright's disease, at least until further investigation has shown that the hypertension is due to some other cause."

Stone[19]: "Since the diastolic pressure measures the peripheral resistance it is a better index of hypertension than the systolic pressure. A sustained diastolic pressure of from 100 to 110 signifies hypertension. The diastolic is less influenced by physiological factors than the systolic pressure."

As before said, there are few statistics indicating the high and low limits for diastolic pressures. In reviewing the literature, however, one is impressed with the fact that the diastolic rarely exceeds 100 mm. Hg. unless there is some pathological condition which will account for it.

An analysis of our cards with diastolic records has been made by separate years, to show the changes in pressure in both the diastolic and pulse pressures, as the examiners became more expert. In order to increase the number of cases we had 1,103 available cards for 1915 partially analyzed, making a total of 5,018 diastolic records.

Table VII.

Ages	1912-13, 1,216 Cases				1914, 2,699 Cases			
	Cases	Systolic	Diastolic	Pulse Pressure	Cases	Systolic	Diastolic	Pulse Pressure
15–19	16	120	85	35	24	122	85	37
20–24	89	123	88	35	222	122	87	35
25–29	235	124	92	32	491	123	87	36
30–34	249	125	92	33	652	125	89	36
35–39	244	128	95	33	561	126	90	36
15–39	833	125	92	33	1,950	125	89	36
40–44	188	128	95	33	402	129	92	37
45–49	113	130	99	31	221	129	91	38
50–54	52	131	96	35	86	133	94	39
55–59	21	139	108	31	34	137	100	37
60–64	8	137	108	29	4	141	101	40
65–66	1	140	110	30	2	149	99	50
40–66	383	130	98	32	749	130	93	36
15–66	1,326	127	94	33	2,699	126	90	36

It will be noted in Table VII that the 1914 figures for diastolic pressure are below those of 1912 and 1913, while the pulse pressure has increased—further, there is a rise in diastolic pressure with age similar to that of the systolic, but the pulse pressure remains practically constant during all ages. This is further demonstrated by Table VIII, which is a condensed analysis and includes the 1915 cases.

Table VIII—Combined Diastolic and Blood Pressures

Year	Total Cases	Total Systolic, Mm.	Total Diastolic, Mm.	Average Systolic, Mm.	Average Diastolic, Mm.	Average Pulse Pressure, Mm.
Ages 15–39						
1912–13	833	103,997	76,697	125	92	33
1914	1,950	242,885	172,658	125	89	36
1915	786	98,274	69,268	125	88	37
Total	3,569	445,156	318,623	125	89	36
Ages 40–66						
1912–13	383	49,829	37,340	130	98	32
1914	749	97,151	69,378	130	93	37
1915	317	41,011	28,807	129	91	38
Total	1,449	187,991	135,521	130	93	37
All Years						
Ages 15–39	3,569	445,156	318,623	125	89	36
40–66	1,449	187,991	135,521	130	93	37
Ages 15–66	5,018	633,147	454,144	126	91	35

An examination of the 1915 records in this table shows a further reduction in the diastolic readings and an increase in the pulse pressure, over the preceding years. It is believed that as the examiners become more familiar with taking the diastolic pressure and our records increase in volume, there will be a further reduction in the diastolic figures with an increase in the pulse pressure over that now shown.

An attempt has been made to determine the range of diastolic pressure as shown in Table IX.

In order to ascertain, as nearly as possible, the normal diastolic range we took records from reports completed by some examiners in whose ability to give us proper readings we had every confidence, and 1,458 such records were used giving for all ages a constant range of 36 mm. This is lower than the figures from all the records, but it is felt that these are still too high; that the diastolic range should be greater than the systolic seems hardly possible, as this pressure is more constant and less influenced by emotion, etc. The total range given in this table, it will be noted, is twice the range between the high and low averages.

Table IX—Diastolic Range

Ages	Cases	Average High, Mm.	Average, Mm.	Average Low, Mm.	Total Range, Mm.
1912–1913					
15–39	833	104	92	83	42
40–66	383	111	98	86	50
15–66	1,216	106	94	84	44
1914					
15–39	1,950	97	89	78	38
40–66	747	103	93	83	40
15–66	2,699	101	90	79	44
Selected Examiners' Cases Year 1914					
15–39	1,043	96	87	78	36
40–66	415	101	91	83	36
15–66	1,458	97	89	79	36

From our figures the diastolic range is then 18 mm. above and 18 mm. below the normal average for any given age.

Table X—Normal Diastolic Limits

Ages	Minimum −18 mm.	Average Year 1914	Maximum +18 mm.
15–19	67	85	103
20–24	69	87	105
25–29	69	87	105
30–34	71	89	107
35–39	72	90	108
40–44	74	92	110
45–49	73	91	109
50–54	76	94	112
55–59	82	100	118
60–64	83	101	119
65–69	81	99	117

Using this range Table X was prepared in an endeavor to show the minimum and maximum limits within which this pressure may be considered normal. It is believed that the limits as given here are excessive and for this reason Table XI was constructed considering from 25-60 mm., the normal pulse pressure and using the average systolic pressures as a basis.

Table XI—Normal Diastolic Limits by Pulse Pressure

Ages	Average Systolic	Minimum Diastolic −60 mm.	Maximum Diastolic −25 mm.
15–19	119	59	94
20–24	122	62	97
25–29	123	63	98
30–34	124	64	99
35–39	125	65	100
40–44	127	67	102
45–49	129	69	104
50–54	132	72	107
55–59	135	75	109
60–64	137	77	112

These limits are within those given in Table X and are probably nearer the truth. It is evident from Table XI that a maximum diastolic pressure over 100 mm. under age 40 or over 110 mm. above that age must be looked upon as abnormal. This agrees with quotations previously made.

Table XII shows the average pulse pressure for the different years and indicates that it is slightly

larger over age 40 than under; also that with greater accuracy on the part of the examiners it is increasing.

TABLE XII—PULSE PRESSURE

Ages	1912-13 Mm. Hg.	1914 Mm. Hg.	1915 Mm. Hg.
15-39	33	36	37
40-66	32	37	38
15-66	33	36	37

In concluding this paper I wish to quote from a recent article from MacWilliam and Melvin[20], dealing with the diastolic blood pressure:

"The estimation of diastolic pressure by the auscultatory method is a process which takes very little time and trouble and yields very definite and valuable information. The procedure is one calculated to produce less circulatory disturbance in abnormally sensitive cases than the stronger (obliterative) constriction of the comparatively large vascular area involved in systolic determination.

"Moreover, diastolic estimation is much less, if to any comparative extent, at all, affected by the main sources of fallacy in systolic estimation . . . variation in the resistance of the arterial wall, possibility of reflected waves, etc.

"Even comparatively slight changes in diastolic pressures, unless dependent on alterations in the pulse rate, are of considerable significance as indications of circulatory conditions (changes in peripheral resistance, etc.).

"Diastolic pressure estimation by the auditory method is not only as simple in application as the systolic estimation, but is comparatively little, if at all, influenced by many of the complications as regards local conditions, etc., which may in some cases introduce serious fallacy into systolic estimations; it also causes less disturbance (circulatory, etc.), in very sensitive subjects, much less constriction of the limb being needed.

"Changes in diastolic pressure, of relatively small amount, unless dependent on an altered pulse rate, are of much significance as indications of circulatory conditions."

STIGMATA OF TUBERCULOSIS.

A STUDY OF CERTAIN ANATOMICAL DEFECTS, THEIR ORIGIN AND SIGNIFICANCE, IN RELATION TO THIS DISEASE.

BY CHARLES J. HOLEMAN, M.D.,

P. A. SURGEON, U. S. NAVY.

To the layman, it is no difficult matter, here in their adopted haunts to "spot the lungers," even by a casual glance. What a boon it might prove should it be possible for the medical man with equal facility to select those who are especially predisposed to tuberculosis before infection actually occurs!

True, there have been described "tuberculous types" of individuals, presenting two widely different appearances—the excessively fair, fine-haired, blue-eyed, *spirituelle* sort of persons, and the thick-lipped, broad-nosed, pasty-skinned sort. Yet after viewing the subjects of actual infection, this classification seems scarcely justified.

Are there any easily observable physical characteristics that may serve to guide the practitioner in advising his patients to be on guard, or at least in keeping himself on guard against the appearance of this disease? Or, if he be concerned in the recruiting of the various military services, to make him especially wary as he passes upon applicants for enlistment?

During several years of observation of the tuberculous, the fact that the majority of them exhibit those signs that are described as stigmata of degeneration has constantly borne itself in upon me. And of these stigmata, the most common, as well as the most striking and easily observed, are the various malformations of the pinna. Next to these, ill formed palates, and gross facial asymmetries abound.

Search of the records of 189 cases that have been examined by myself and discharged from this hospital prior to December, 1914, revealed a note of such stigmata in 117 cases, or 61.9 per cent. Of 233 patients now in the hospital, 188, or 80 per cent., show stigmata of the kind mentioned. The following table shows the result of the examination of these patients, including 210 whites and 23 others (Asiatics, Negroes, Filipinos, Chamorros, one Kanaka, and one Costa Rican):

	Total Examined	Total Showing Deformities of Ears, Palate or Face	Total Showing Deformities of Ears	Percentage of Deformed Ears	Total Showing Deformities of Palate	Percentage of Deformed Palates	Total Showing Facial Asymmetry	Percentage Showing Facial Asymmetry	Total Showing Combinations of Deformities	Percentage Showing Combinations of Deformities
Whites	210	169	154	73 3	47	22 4	24	11 4	70	33 3
Others	23	19	16	69 6	3	13	2	8.7	5	21.7

As it was chiefly deformities of the pinna that inspired this examination, it seems worthy of note that in addition to the numerous irregularities and defective mouldings that were observed the following classical types were encountered: Darwin, 16;

Wildermuth, 16; Stahl No. 1, 11; Blainville, 7; Morel, 5; Stahl No. 2, 2.

In the first class are included the large number of cases that showed asymmetries between the two sides, but one of which showed an unduly prominent Darwin tubercle; in no instance were cases included concerning which a notation like "approach Morel type," etc., was made, but only those believed to fully answer the classical description.

Levy[1] states that 75 per cent. of the tuberculous have deformities of the nasal chambers.

It does not appear fanciful that these manifestations of external physical imperfection should be accepted as indices of defective, or at least poorly resistant, viscera. On the contrary, it would seem most reasonable that if these stigmata (aplasias and developmental retardations) indicate a likelihood that mental instability may be present and eventuate in psychosis, should the individual find himself in unfavorable environment; they should also indicate that visceral aplasia or other defect resultant from malembryopathy is present and may render such individual unduly susceptible to infectious influences and therefore more likely to become tuberculous.

The fact that the work of Lombroso has apparently been, to a degree at least, discredited, does not mean that these accepted stigmata have lost or indeed altered, their significance.[2] It was never considered that the possessor of a Blaineville ear was therefore mentally defective. The significance of its possession is that, if found in conjunction with other stigmata, its owner should be more carefully observed than the ordinary individual and care taken, should his nervous system show any sign of instability, that the stresses of life be not permitted to bear too heavily upon him. So, too, this same individual, exposed to the same dosage of tubercle bacilli and subjected to the same exposure and exhausting labor as a completely normal person, is far more prone to contract tuberculosis.

On the basis of this theory, then, may we not conclude that the "stigmata of degeneration" of the psychiatrist may be accepted as "stigmata of susceptibility" by the phthisiologist. Should further evidence be demanded, the fact that the insane—the possessors of confirmed external stigmata—are of all individuals most preyed upon by tuberculosis is confirmatory. Stoddart,[3] in his recent book, says (italics in this and following quotations are mine):

"The death-rate from phthisis in our large [British] county asylums, as compared with that in the general community, is so alarming that a few years ago the Medico-Psychological Association appointed a special committee 'to make some practical suggestions for the isolation of phthisical patients in asylums.' This action of the Association was the direct outcome of a prize essay by Dr. F. G. Crookshank, 'On Phthisis Pulmonalis in Asylums,' and a paper by Dr. Eric France on 'The Necessity of Isolating the Phthisical Insane.'

"Dr. Crookshank pointed out in his essay that, although not more than 7.5 per cent. of the insane are phthisical on admission, the official death-rate from phthisis among the insane, which is probably too low by one-third or one-half, is 14.6 per 1,000 of the average resident population in English asylums; whereas the phthisis death-rate among the general population of England and Wales is 1.46 per thousand living. *In other words, death from phthisis is ten times as frequent in asylums as it is among the general population.*

"The causes of the frequency of phthisis in asylums are not far to seek; for it is found, on examination, that in most of our large county asylums every etiological factor is at work.

"In the first place it has been pointed out by Dr. C. J. Shaw, assistant medical officer to the Murthly Asylum, that *the insane are, as a class, more liable to tubercular infection than the sane*, their capacity of resistance to tubercle, as estimated by the opsonic index, being deficient (0.8 to 0.9). The opsonic power is especially deficient during the acute stages of mental disorder and in cases of dementia præcox and general paralysis."

Maurice Craig,[4] in the section of his book devoted to Insanity and Physical diseases, says:

"The relationship of phthisis to insanity is very close. In one family will be found some insane and some phthisical members. A tubercular parent may beget children who later become insane. When the two diseases are associated in the same individual, it is necessary to consider which appeared first. Phthisis has been in the past, and is even at the present day, one of the commonest causes of death in our large asylums. The great majority of these patients develop phthisis in the institution—that is to say, *the tubercular disease is secondary to the insanity.*"

American authorities concur; thus Huber:[5]

"It seems that a disproportionate number of the insane develop tuberculosis during their stay in asylums. One account states that in seventy-four consecutive cases of pulmonary consumption, in ages between twenty and sixty-two years, only three had evidence of this disease before admission to these institutions. It is furthermore observed that those who enter an asylum with tuberculosis have little chance of recovery while they are inmates.

"It seems that tuberculosis is apt to follow insanity. It does not precede the latter. Several phases of life among the insane, which do not obtain in normal circumstances, would explain this condition of things. Many will not complain or tell of their symptoms, and thus do not for a time manifest tuberculosis. Indoor life, even cell life, is essential for many of them. . . . Then the tissues of many asylum inmates are apt to be vitiated and of lowered tone, so that they are predisposed to infection, tubercular or otherwise; this is particularly so of the melancholic and demented types.

". . . In insane asylums two sorts of tuberculous subjects are encountered—those who have suffered from the disease before their admission, in whom the condition progresses slowly, *and those who become infected after admission, in whom the disease progresses rapidly.*

"Dr. James Greenwood, of the Southwestern Insane Asylum, Texas, considers tuberculosis by far the most serious of the asylum diseases. . . . The asylum with which this observer is connected has a tuberculosis record of twenty-one plus per cent., or eighty-five among 392 deaths during the twelve years of its existence. Nine-tenths of such patients are between twenty and fifty-five years of age, and eleven-twelfths of the deaths from tuberculosis are found to have occurred during these years.

"The total death-rate per thousand in the United States for this period is about ten, of which 4.4 to 4.8 are due to tuberculosis. In this asylum for twelve years past there has been an average yearly death-rate of thirteen per 1,000 among the inmates, due to tuberculosis alone. *This is three times as many as are caused by tuberculosis in the United States within the age limits stated.*"

White,[6] in the report for the Government Hospital for the Insane, for 1914, gives the following table.

In view of this relation between mental disease, tuberculosis and external stigmata, is it not likely that there is some fundamental cause operating upon the tissues at a time when ectoblastic (furnishing central nervous system and skin with its appendages) and entoblastic (furnishing bronchopulmonary system) derivatives were still directly subject to the same influences, that is prior to the primary differentiation of the layers? And does not blastophthoria, as described by Forel,[7] which at the instant of conception stamps upon the fecundated ovum irradicable inability to develop perfectly, satisfactorily account for these phenomena?

Of blastophthoric influences alcohol easily stands first. Let us then examine the influence of alcoholic ancestry on insanity and on tuberculosis.

PULMONARY TUBERCULOSIS IN THOSE WHO DIED DURING THE YEARS ENDED JUNE 30, 1885–1914

Concerning insanity, Peterson urges that: "Hereditary equivalents, *including drunkenness*, should be sought in determining the factor of heredity in investigating a case of insanity." [8]

The following table, prepared by Otto Diem,[3] in the study of heredity, sufficiently illustrates the place of prenatal alcoholism in the production of insane:

	Parents of 370 Sane	Parents of 370 Insane
Insanity	17	68
Alcoholism	32	63
Senile dementia	1	10
Eccentricity	22	67
Suicide	2	4
Total abnormal	74	212
Total normal	666	528
Total of all parents	740	740

The following observations are made by Craig:[4]

"In the families of alcoholic parents nervous diseases of all kinds appear; the child may be imbecile from birth, or may early develop epilepsy, and in time may help to swell the already large number of insane. Children of alcoholic parents are not uncommonly vicious in their habits and criminal in their tendencies."

The striking fact is noted by Forel[7] that:

"The recent researches of Bezzola seem to prove that the old belief in the bad quality of children conceived during drunkenness is not without foundation. Relying on the Swiss census of 1900, in which there figure 9,000 idiots, and after careful examination of the bulletins concerning them, this author has proved that there are two acute annual maximum periods for the conception of idiots (calculated from nine months before birth): the periods of carnival and vintage, when the people drink most. In the wine-growing districts the maximum conception of idiots at the time of vintage is enormous, while it is almost nil at other periods. Moreover, these two maximum periods come at the time of year when conception is at a minimum among the rest of the population; the maximum of normal conceptions occurring at the beginning of summer.

"If these facts are confirmed by further research, we may conclude that even acute alcoholism has a blastophthoric action. We may, therefore, assume that when a germinal cell leaves its gland at the moment when it is impregnated with alcohol, and achieves conjugation, it is unable to return to its normal condition, for want of opportunity to be completely and promptly cleansed by nutrition and the circulation. This explains how it may transmit to the individual which develops from it all kinds of taints and defects."

And in summing up the relation of alcohol to disturbance of sexual function, the same author says:

"Creation of hereditary alcoholic blastophthoria [occurs], either as the result of a single drinking bout, or from habitual drunkenness. *The offspring tainted with alcoholic blastophthoria suffer from various bodily and physical anomalies*, among which are dwarfism, rickets, predisposition to tuberculosis and epilepsy, moral idiocy and idiocy in general, a disposition to crime and mental diseases, sexual perversions, loss of suckling in woman, and many other misfortunes."

Of some value in this connection are the following tables, prepared by Thomas,[9] giving the results of the application of the Binet tests to certain criminals, confined in the Naval Prison at Portsmouth, N. H.:

(A) CONVICTED OF SODOMY AND SCANDALOUS CONDUCT

Mental Age	Cases	Average Years in School	Alcoholic	Abnormal Family History
			Per cent.	
10	1	5½	70	Tuberculosis, 4 Alcoholic, 3 Epilepsy, 2 Insane, 1
11	3			
12	2			
13	4			

(B) CONVICTED OF THEFT

9	1	7	30	20 per cent. alcoholic
10	1			
12	2			
13	6			

(C) MEN WHO HAVE LOST ALL GOOD TIME BECAUSE OF MISCONDUCT

10	1	5	66	Feeble-minded, 1 Tuberculosis, 2 Epilepsy, 1
12	4			
13				

Here, though the number of cases is small, alcohol and tuberculosis seem to rank about as high as actual mental disease as blastophthoric factors.

In the earlier annual reports of the Henry Phipps Institute at Philadelphia, most interesting data, pertaining to alcohol in its relation to tuberculosis, were recorded. In the report for the year ending February 1, 1908 (the last I have at hand), concerning the alcoholic histories of patients treated at the institute, the following appears:

SUMMARY FOR FIVE YEARS.[10]

Alcoholism in patient..... 921 (20.62%)
Alcoholism in preceding generation. 901 (20.17%)
Out of 4,466 cases.

Are not these facts, gleaned from such widely different sources, and set down with such various purposes, sufficient to condemn alcohol as a powerful blastophthoric agent, and at the same time, to show that its degenerative influence may be exhibited in the form of insanity, tuberculosis, or criminality? Yet it might not be greatly out of place to inquire whether or not these manifestations are truly evidences of blastophthoria. From the lurid statement of a Hobson accrediting 2,000 deaths a day in America to Demon Rum, to urgent claims of the brewers and distillers that alcohol is a food, the use of which is justified by the jovial ex-

ample of every generation, since Noah celebrated winning the 300-cubit ark trophy, all sorts of statements concerning the results of alcohol have been made. The following, quoted from the paper from W. F. Boos,[11] on the relation of alcohol to industrial accidents and to occupational diseases, is surely authentic and to the point:

". . . As a result of other German studies, it was determined that if the accidents caused by the use of alcohol could be eliminated, 7 per cent. of all accidents would be prevented.

"Most industrial houses confine their efforts to the prohibition of intoxication or the use of alcohol during working hours. They have, however, no effective method to control surreptitious drinking up to the point of actual intoxication. When a workman has taken enough to become intoxicated, this fact is immediately self-evident, and the offender is promptly ejected. Gross intoxication may therefore even act in a measure as a safeguard against accidents. But the damage may have been done long before the man is really drunk. If, on the other hand, he is an habitual drinker who never gets drunk, he forms a source of constant danger to himself and to his fellows. . . . Monday accidents result from the paralyzing effect of a Saturday night and Sunday debauch, the 'hang over' from which may last for from twenty-four to forty-eight hours. The victim of the 'hang over' appears normal to the casual observer; *he is not, however, in complete control of his faculties, and he is therefore much more liable to have an accident.*

"A study of the industrial accidents occurring in Zurich, during the years 1900 to 1906, inclusive, shows that the average for accidents on other week days except Monday is 15.7 per cent., while the average for Monday is 22.1 per cent.

"The habitual daily drinker is perhaps the greatest source of danger, for although the quantities of alcohol he takes each day may not suffice to produce intoxication, they suffice, nevertheless, considerably to reduce his alertness. *Drinkers of this class suffer loss of acuteness of hearing and of vision; in fact, all their mental processes are retarded (experiments of Joss, Smith, Kraepelin, Aschaffenburg). Consequently these men are less careful and accurate in their work, and are also slower to perceive or appreciate danger.* . . . The continued use of alcohol also retards tissue repair after injuries."

If it is true that alcohol thus profoundly affects the central nervous system, the muscles and the coordinating mechanisms in general, and in addition, produces the scleroses which pathology unerringly places to its credit, how can it be questioned that the generative glands share in the same processes, with the result that their product is defective if not actually diseased?

Among other blastophthoric influences syphilis, lead, and other cachexias are important, as are also tuberculosis and insanity themselves. Perhaps, too, psychic influences, concerning which few data are available, as fright, fear, and anger on the part of the mother might be included.

Should these facts and deductions be accepted, then it would appear that the more marked stigmata would be more apt to be precursors of actual insanity or of more hopeless tuberculosis. In the one case, this is accepted as true—the insane ear, for instance, being more truly a symptom than a stigma. While I have not preserved the data, I am convinced that the death rate among those patients showing more marked stigmata at this hospital has been extremely high compared to those who show slight or no such defects. Of the nine patients now in the hopeless ward, all show stigmata of the kind referred to in this paper.

If, however, one is inclined to reject the blastophthoric theory, then there is still to be explained in some other way the inevitable fact that the alcoholic (or other grave) iniquity of the father is visited upon the children in tremendously increased susceptibility to tuberculosis, insanity, and criminality. And I submit the statement that their inheritance, while it may be written on fleshly tables of their hearts, giving rise to pernicious instincts and a tendency to unhealthful or vicious habits, is also written upon their features, in stigmata so plain that he who runs to their aid in the time of mental stress or physical strain may read, if he but will.

Conclusions.—1. Stigmata of degeneration may be considered as stigmata of susceptibility to tuberculosis.

2. Extreme stigmata in tuberculosis indicate a less favorable prognosis.

3. Stigmata of degeneration, central nervous system and pulmonary (and probably other visceral) defects have a common blastophthoric origin, alcohol ranking high.

TRANSIENT ATTACKS OF MANIC-DEPRESSIVE INSANITY.

By MENAS S. GREGORY, M.D.,

NEW YORK.

DIRECTOR, PSYCHOPATHIC AND ALCOHOLIC SERVICES, BELLEVUE HOSPITAL; PROFESSOR OF PSYCHIATRY, POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

Mild and short attacks of a manic-depressive psychosis which may closely resemble the normal variations in mood, have been described by writers on psychiatry; but, for the most part these reports have been of attacks of more than a week's duration. I desire to place on record, not attacks of a week, but of days, and even of only a few hours' duration. Such attacks, I am led to believe from a review of the literature, are rare. In Stransky's[1] recent extensive monograph on manic-depressive psychosis, such short attacks are referred to as possibilities, but none is recorded which shows the disorder in short attacks only.

Furthermore, I find no expression of opinion that such attacks are common. In fact, the emphasis seems to be the other way. Thus Weygandt[2] speaks of short attacks of a week's duration, and suggests the possibility of those of even a day; whereas, from my experience in the Psychopathic and Alcoholic Wards of Bellevue Hospital, I am led to the conviction that such very fleeting attacks are by no means rare; in fact, are quite frequently observed.

In 1908[3] I called attention to a special group of allied manic-depressive states, which I termed atypical, and which consisted of cases of very short, almost transitory duration. These patients, I then pointed out, were suffering from some form of atypical intoxication or pathological drunkenness. In addition to their toxic symptoms, they presented

the characteristic syndrome of a manic-depressive psychosis, such as typical flight of ideas, irritability, loquaciousness, and motor restlessness. In some of these cases, the manic-depressive symptoms persisted after the ordinary signs of intoxication had subsided, often within twenty-four hours, and the patient cleared up entirely.

At that time I said that the mental state of these patients presented special difficulties from the standpoint of diagnosis, and that one might consider them on the one hand as the reaction of a manic-depressive personality to alcohol, or, on the other hand, as short attacks of manic-depressive psychosis, complicated with alcohol. After further observation I now feel that the latter viewpoint is more correct, and that these are instances of typical manic-depressive attacks in which alcoholism has been an accidental or incidental factor.

It is also by reason of this very feature of the accidental alcoholism that the real nature of the difficulty has been hidden, and, furthermore, the alcoholism has been at the same time the factor that has served to emphasize the features of a manic-depressive psychosis, which, without a certain accidental exaggeration, might not have attracted attention.

From their fleeting nature and transitory character, these mild attacks of manic-depressive psychosis rarely attract the attention of those with whom the patient comes into immediate contact, and at times they even fail to make any impression on the patient himself, unless the symptoms are accentuated by some outside factors, among which, as we have seen, alcoholism is the most common.

It is due to this complicating alcoholism that these patients find their way into the alcoholic wards, where they constitute the majority of the formerly so-called "pathological drunkards," "dipsomaniacs," and "periodic drinkers." In the alcoholic wards of Bellevue Hospital this underlying mental disorder is seen in fleeting attacks lasting from a few hours to a day or two, when it had been regarded as "pathological drunkenness." If the attack had been of longer duration, lasting from several days to a few weeks, it had been looked upon as "dipsomania," or as a phase of an alcoholic psychosis.

All of the phases of a manic-depressive psychosis can be observed. Here one may see excited, depressed, and mixed states, although the last are most difficult to recognize. These patients have been admitted and discharged from the hospital many times, without the nature of the real, fundamental, mental disease having been recognized. They swell the number of so-called "rounders" and "repeaters" found in the alcoholic wards.

The careful anamnesis of these patients shows that at first they drank only periodically—the so-called periodic drinkers. Although some of them still remain such, many of them have gradually become habitual and continuous imbibers as well, with episodic outbreaks of the fundamental mental disturbance. Many of the so-called alcoholic cures, semi-reputable as well as charlatanistic, derive their chief support from this type of patients.

A few case histories, selected from a large number, illustrate the different transitory phases of the manic-depressive psychosis as it appears in the alcoholic wards.

CASE I is an example of the short excited attacks, which are ordinarily called pathological drunkenness:

P. S., 42 years old, has been coming to the alcoholic wards about once every six to eight weeks for the past eight years. He is one of the notorious repeaters, who is known as an "excited, violent, and ugly drunkard." On admission, with very few exceptions, he is alert, talkative, flighty, irritable, quarrelsome, and meddlesome, and makes many keen and cutting personal remarks; he becomes violent and assaultive at times, and requires restraint. His pupils are dilated; his skin is moist; an alcoholic tremor is present, but he shows none of the psychic nor motor incoordination characteristic of alcoholic intoxication. He has never suffered from any hallucinosis and has never been delirious except once, two years ago, when he also had pneumonia. His excitements never last longer than twenty-four hours. The day after his admission he is quiet, mild-mannered, and gentle, and appears to be ashamed of his previous conduct. He says that he does not begin to drink because he likes it, but that "a queer feeling comes over him," which he describes as a sudden feeling of being unusually happy, and then he wants to have a "good time." One maternal aunt has had mental trouble. For the last two years he has also been drinking moderately between attacks.

CASE II is similar to the former, except that the alterations of excitement and depression have been apparent.

M. S., a robust female, 32, domestic, born in Ireland. The meager family history as given by the patient is negative. She has frequently been an inmate of the alcoholic and prison wards since 1906. At times she is very excited and boisterous, and must be brought to the hospital by several policemen. At almost every visit she disables one or more of the policemen who bring her to the hospital. She has spent a goodly part of several years in the workhouse, from which she was, at one time, committed to the Matteawan State Hospital, where she remained several weeks. She is talkative, alert, flighty, destructive, abusive, quarrelsome and meddlesome. This condition usually lasts from twenty-four hours to two or three days. She shows signs of alcoholism, such as dilated pupils, moist skin, tremors, coated tongue, etc. She has never been delirious and has never suffered from hallucinosis. Occasionally she comes as a voluntary patient, when she is depressed and despondent, quiet and inactive, talks very little and has made several attempts at suicide, outside as well as in the hospital. On some occasions she has ideas of self-reproach and unworthiness. She always exhibits signs of over-indulgence in alcohol, but never to the extent of delirium or hallucinosis.

CASE III is an example of one who has short attacks when he would be considered a pathological drunkard, and longer attacks which were incorrectly diagnosticated as dipsomania.

H. A., male, native of New York, now 48 years of age, a graduate of Yale, has been admitted to the alcoholic wards fifteen times since 1904, and eighteen times to the psychopathic wards since 1903. He is always very much excited on admission, talks a great deal, is flighty, irritable, and threatening, shows considerable motor activity in spite of a state of acute intoxication on admission. He is keen, alert, meddlesome, and quarrelsome. In general appearance he is unkempt and uncleanly, which is consistent with his alcoholism. His face is flushed, the pupils are dilated, the tongue is coated and tremulous. There is marked general tremor at times, suggesting the approach of a delirium, but he has never been delirious. On one occasion he had an attack of hallucinosis, which disappeared in a short time. His attacks last from two days to a week, and on several occasions they have lasted for several months. He has tried all of the alleged cures, but his aged mother, who was a literary woman, was told that these cures were not successful because of the weakened will power of the patient. When the attacks are of longer duration, he has been considered to be suffering from an alcoholic insanity, and has been repeatedly committed to sanatoria and State hospitals, where he remains a short time.

Because of his irritable and quarrelsome disposition at the onset of his disorder, he has, on several occasions, been committed to the workhouse for periods of three to six months, on charges of disorderly conduct. Since the death of his mother, two years ago, it is significant to note that he no longer comes to the hospital,

but is sent to the workhouse as an intoxicated and disorderly person. When his attacks are very short, he is looked upon as a quarrelsome drunkard, as I have already stated, but when they are of longer duration, he is committed to a sanatorium as suffering from an alcoholic psychosis.

CASE IV is quite similar to the preceding as regards the duration of the mental disorder, but it differs from it, however, in that he has alternate attacks of depression and excitement, and very frequently the attack of excitement is preceded by one of depression.

P. M., 42, born in Ireland, laborer. His mother was once melancholy. He has been admitted eighteen times to the alcoholic wards and four times to the psychopathic wards since 1908. He has been regarded as an alcoholic repeater, who, at times, becomes insane as the result of his alcoholic excesses and is then sent to the psychopathic wards. He is excited, as a rule, on admission. His attack usually lasts from a day to a week, and at times is longer, when he must be committed to a State hospital. He is active, talkative, irritable, has great notions about himself, maintains that he knows as much as the physicians and nurses, and offers suggestions about the treatment of the patients. He is officious, meddlesome, and may become assaultive at the least provocation. He shows all of the physical signs of a recent alcoholic debauch. There is no clouding of consciousness, no disorientation, and he has never become delirious. As a rule, however, he shows an hallucinosis of a peculiar character which shortly disappears. He maintains that all sorts of inanimate objects, such as the wall, the force of gravitation, the bed in which he lies, and the pictures on the wall, talk to him. He may clear up in two days, or he may suddenly develop a state of depression when the mental picture is the antithesis of his previous condition. He is then depressed, quiet, inactive, complains of headache, inability to think, and shows no interest in his surroundings. This condition may also disappear in two days and he is discharged recovered. Between the attacks he is a total abstainer, and claims to have a pronounced distaste for alcohol. His stated reason for drinking is that he suddenly feels hopeless, melancholy, and that he cannot do anything. He drinks to cheer up. I quote from his history while in the hospital during an attack in December, 1911. "His sister says that he suddenly came home drunk, remained in bed for two days, was downhearted and melancholy. He thought that everyhody was against him and that they wanted to get him out of the way. On the midnight of the second day, he suddenly brightened up, sang in a loud voice, and was brought to the hospital." When admitted he was in a typical attack of excitement. He said that the reason why he was singing was because, when at home in a melancholy condition, suddenly "the joy of gladness came to his heart" and he could not stop singing. He recovered in six days. This man has been regarded as a troublesome drunkard and discharged from the alcoholic wards eighteen times. and committed twice to State hospitals since 1908.

CASE V may be cited as a mixed phase of a manic-depressive psychosis.

W. L., 57 years old, born in the United States, clerk by occupation. He has held important positions in labor unions, and in many respects is above the average in intelligence. He is very temperate in his habits between the attacks. This man has been admitted to the alcoholic and psychopathic wards eleven times since 1907. As a rule he averages three attacks a year, mostly in the summer months. On admission he exhibits a picture of anxious restlessness. He is very active, talks a good deal, is distractible, and at times somewhat flighty. Emotionally however, he is always sad. He has ideas of ruin and unworthiness: "Why is everyone so kind to him; he does not deserve it;" "he had no intention of drinking;" "something like a shadow came over him;" "he felt out of sorts," etc. He shows all the signs of recent alcoholic excesses—moist skin, dilated pupils, coated tongue, tremor, almost verging on delirium, but has never exhibited delirium nor hallucinosis. Two out of his eleven attacks were excited periods. He was jovial, singing, dancing, happy, optimistic, restless, meddlesome, flighty, etc. These attacks last, as a rule, three or four days, after which he develops insight into his condition and seems greatly distressed. This patient being an intelligent man, I was able to investigate his state of mind immediately before he began to drink. He stated that at times he feels as if a shadow suddenly comes over him, which makes him, as it were, absolutely helpless. He cannot think, has no energy or initiative to do anything, feels exceedingly blue. He remembers that in his first attack, while in this condition, he thought of the oft repeated phrase, "have a drink and cheer up," and then, as it was convenient for him to do so, he began to drink. That since that time he begins to drink whenever he experiences the same peculiar feeling. That during his "joyful attacks" (the excited attacks referred to) he drinks because he feels so happy. One of his attacks was of longer duration, requiring treatment in a sanatorium for six weeks.

CASE VI is another example of a mixed phase.

M. A., a woman, 35, family history unascertained. She has been admitted twelve times to the alcoholic and four times to the psychopathic wards since 1907. On admission she is always perfectly quiet and mute. It is impossible to get any response from her. She assumes an attitude of haughty elation, with an expression which varies from a self-contented smile to ecstacy. She seems to observe her surroundings and understand what is said to her, but gives no response to questions. In other words, a picture of psychomotor retardation, with emotional exaltation. This condition may last from twenty-four hours to three days, when she begins to make random, flighty remarks, or suddenly screams, and occasionally the clinical picture may change to one of typical excitement.

On admission she shows physical signs of alcoholism, except that the pupils are contracted and her knee jerks exaggerated. However, the serological examination is negative and there is no evidence of any organic disease. She recovers, as a rule, within a week. Two of her attacks were of longer duration and she was committed to State hospitals. This patient is also one of the notorious repeaters.

CASE VII, my last patient to be cited, was admitted to the hospital on April 24, 1912. He is of interest in that he has a history of having had definite attacks, which are known to be independent of alcoholism, because the character of his occupation is such that for stated periods he had no opportunity to drink.

J. S., 23 years old, an oiler on a tramp steamer, born in England. His father was a periodic drinker and would become excited while drinking. The patient had variola and mastoid disease some years ago. For the past five years he has had periodic attacks of drinking which last from eight hours to several days, and which are repeated a number of times a year. In the interim, he is a total abstainer, and has no taste for alcohol. At the onset he becomes depressed and, as he states, has no ambition, no will power to do anything, feels as if his mind had stopped working. He begins to drink, and may remain in this state for twelve to twenty-four hours and he then recovers. Or, after the usual initial stage of depression, when he begins to drink, instead of remaining depressed, he suddenly may become excited, talkative, quarrelsome, and destructive, and this condition may also last from twelve to twenty-four hours. Almost all his attacks ashore are associated with alcoholism. This patient being an oiler on a steam vessel, is at sea the greater part of the time, and has had a number of attacks there. These latter attacks have been precisely the same as the others, with the exception of the absence of the alcoholic features. That is, he suddenly becomes depressed, loses ambition and will power, and is unable to think or do anything. He states that his mind would suddenly become "blocked;" this would last from twelve to twenty-four hours, and then he becomes normal. He remembers every detail and suffers no loss of consciousness. He states in addition, that some of his attacks take the form of great activity; he becomes very energetic and wants to do the work of two or three men; becomes meddlesome and interferes with the work of his shipmates, so that they keep him in his bunk for a day or two, until the attack passes. It is interesting to note that during these attacks at sea he has no

craving for alcohol, and claims that he does not even think of it.

I have chosen these examples from a great number, as being typical, in that most of these patients have also shown attacks of longer duration, which were unmistakable attacks of manic-depressive psychosis. There are, however, many patients in whom the attacks are of fleeting character, from a few hours to several days' duration, and remain so throughout.

The purely depressed phases of manic-depressive psychosis associated with alcoholism are equally as frequent, I believe, as the excited ones, although it is more difficult to recognize them. An excited case will compel attention, whereas the depressed type may easily escape notice, because of its resemblance to a toxic depression and hallucinosis.

As a rule, manic-depressive patients do not suffer from alcoholic delirium. This is especially true of those with excitement. As has already been stated, most of these patients drink periodically only, and the taking of alcohol is an incident of the psychosis. A relatively small quantity of alcohol in addition to the exhilaration of the manic-depressive condition so excites the patient that he immediately attracts attention and is brought to the hospital before he has had the opportunity of taking a sufficient quantity of alcohol, or drinking long enough to produce delirium. Even those who use alcohol in the interim between the attacks are not heavy drinkers as a rule.

In the depressed types, however, although alcoholic delirium is equally infrequent, hallucinosis is quite often met with. In the depressed phases, excessive or prolonged taking of alcohol, likewise, does not occur, but, for an entirely different reason. While the exhilaration which is characteristic of the manic phase is lacking here, the general retardation which is the striking feature of the depressed stage prevents the ingestion of much alcohol, hence the infrequent occurrence of delirium. It may also be pointed out that some of the depressed cases may begin with an excited or mixed phase, and rapidly change into depressed types.

In considering the differential diagnosis, especially from uncomplicated alcoholism or alcoholic psychosis, it is of interest to note that manic-depressives are not fearful and apprehensive, but rather depressed and despondent. They react not at all, or less actively to hallucinations. The content of the hallucinations is less absurd, and as a rule is based upon some actual experience of the patient. Manic-depressives never plead for their lives, stating that they are going to be shot, cut up, poisoned, burned alive, electrocuted, etc. There is always a trace of self-reproach; people talk about them, and accuse them because they deserve it; "they have blundered in the past"; "they deserve their punishment." The manic-depressive is inactive and does not show the apprehensive restlessness of the typical alcoholic hallucinosis. There is no confusion or disorientation. Suicidal thoughts and attempts at self-destruction are very common.

Transitory attacks of a manic-depressive psychosis which are not associated with alcoholism, I think, are also very frequent, although it is difficult to demonstrate them. As has already been stated, the milder attacks pass unobserved, even by the patient himself, unless his conduct calls attention to it. Excited cases of this class are usually regarded by physicians as hysteria, or as psychic epilepsy. The milder depressed cases are looked upon by physicians as attacks of billiousness, liver trouble, blues, sick headache, migraine, neurasthenia, psychasthenia, etc.

The following case may be cited as an example in which short attacks of manic-depressive psychosis may be accentuated by other factors than alcohol:

Case VIII.—A young girl of 19 has had attacks of depression and excitement, which are coincident with the menstrual epoch, beginning shortly before and ending with its cessation. She was admitted to the hospital three times during periods of excitement. Since her discharge she has been employed in one of the hospitals as a waitress, and we learn that she suffers from short attacks of depression and excitement, which occur independently of menstruation, and are of so mild and fleeting a character that they do not necessitate her being brought to the hospital. Some of these attacks are only an hour or two in duration. While at work she suddenly sits in a chair and states that she cannot do any more work; will only answer questions in monosyllables, complains of her head, and at times appears bewildered and unable to leave her chair. She remembers, however, everything that transpires, and states that she has a queer feeling which makes her unable to think, speak, or do anything. These attacks had been looked upon as hysteria, coincident with menstruation.

As in the cases associated with alcoholism, patients may associate their attacks with other conditions. For example, a patient of mine, whenever he has a short attack of excitement, leaves his business and takes the first train for a neighboring city. He knows that he is taking the train for that city, and after the attack passes off, he is able to give a detailed account of his trip. He feels happy and restless, active and jovial, and has an irresistible impulse to go to that city because he had a pleasant experience of a sexual character there some years ago.

Another patient burns up everything having a red color, during these short attacks, as she had an unpleasant experience in seeing the bloody clothes of a relative who was killed in an accident. This patient also had one longer attack which necessitated her commitment to a sanatorium.

Transitory depressed attacks are frequently interpreted by the patient as some common physical ailment. The motor retardation and inadequacy seem to be so much more pronounced than the purely psychic symptoms, that they attract the attention of the patient almost to the exclusion of the latter. In other words, the patient's mind is centered on the motor phenomena, so that he endeavors to find a physical counterpart for his mental disorder. If he realizes his psychic shortcomings at all, he ascribes them to the motor inadequacy, which he has converted into physical symptoms.

Some of these cases are so distinctive that one may speak of them as somatic phases of manic-depressive psychosis. These patients are considered and treated by physicians as suffering from physical disorders, and multiply the number of cures by the various cults after having been unsuccessfully treated by medical men.

I shall give a brief résumé of four cases, illustrative of this phase of the disease:

Case IX.—A man 73 years of age; has been subject to periodic nervous attacks, as he calls them, for over forty years. These manifest themselves in neuralgic pains, generalized as a rule, but more severe in places. He describes them as unbearable, like nerves being torn out of the flesh, etc. Treatment for these pains has been given by various physicians, among whom were specialists in nervous diseases. He had taken innumerable remedies and various treatments, such as electricity, baths, mechanotherapy, for the pains,

especially for those in his lower limbs, which were called neuralgia by his physicians. Three of the attacks, occurring within forty years, were of longer duration, lasting from about two to three months, during which, in addition to the neuralgic pains, he was despondent, frequently thought of, and once attempted, suicide. When closely questioned as to the character of these pains, he will describe them as follows: That they are all over his body—in his eyes, ears, nose, head, and particularly in his arms and legs; that they are not cutting, shooting pains, but more of an ache, lack of feeling, heaviness, nervous pains; that he feels the weight of his limbs, etc. Pressure on the nerve trunks, joints, or any particular part of the body does not increase the pain. There is absolutely no evidence of any organic disease. An analysis of his mental condition shows that he suffers from manic-depressive attacks. This patient has converted the motor retardation into a physical symptom, namely, pain, and because this particular symptom of motor retardation is more prominent in his psychosis, he has ignored his psychic inadequacy, or looks upon it as a sequence of his physical disorder.

Case X.—A woman, 42 years of age, whose mother is said to have had two attacks of melancholia, has been suffering from periodic attacks of, as she terms them, "stomach and liver trouble," during which she is despondent, and has on several occasions seriously thought of suicide. She describes her condition as follows: That whenever she has this indigestion, which comes on suddenly, she becomes very sad, seems to lose all ambition and initiative, cannot do her work as she is unable to concentrate. She has queer feelings in her head, which she describes as lack of feeling and numbness. Physically she is completely tired and worn out and must sit or lie down until she recovers from her attack of indigestion, which lasts from three to five days. During one of her attacks she was brought to the hospital, because she made an unsuccessful attempt at suicide. There is no evidence of any gastro-intestinal disorder. Her mental status shows that she is suffering from a typical attack of a depressed phase of manic depressive psychosis.

Case XI.—An elderly woman, has periodic attacks of depression, lasting from two days to a week, which she ascribes to cardiac trouble. During these attacks she retires to her room, will not speak to members of the family, becomes morose and irritable, and complains of distress in the region of the heart. Her physician states that although she has a slight cardiac murmur, it is not of such a character as to cause the discomfort or the distress complained of. At times there is a history of sudden overactivity, psychic and physical. This patient has a daughter who is suffering from the circular type of a manic depressive psychosis.

Case XII.—A physician suffers from periodic attacks of headache which last for several days, during which he retires to his room. He is quiet, inactive, morose, irritable, and becomes quite despondent. He complains of inability to think or do anything. He describes the headache as a lack of feeling in his head and pressure on top, over the occiput. He has taken coal tar products, and many other remedies for headache, without relief. There is no evidence of syphilis or any organic trouble. These attacks sometimes last one or two days, and on one occasion he was compelled to remain in his room for a week. Here again the patient has converted the psychotic symptoms into a physical ailment, namely, headache.

Finally, it may also be added, that many sudden and unexpected suicides, without any history of previous ill-health or any difficulty, are due to fleeting attacks of a manic-depressive psychosis. I am led to this belief from examination of hundreds of cases of attempted suicides which are annually brought to the prison wards of the hospital.

In conclusion I would present the following summary:

1. Short attacks of a manic-depressive psychosis, ranging in duration from a few hours to several days, are very frequent—I believe much more numerous than longer attacks requiring hospital treatment, but they are difficult to recognize unless accentuated by some exogenous factor.

2. These fleeting attacks are frequently marked by these very exogenous factors and are misinterpreted as mental states, due to the incidental factor, which in reality is merely accidental or incidental to an attack of a manic-depressive psychosis.

3. Alcoholism is the most frequent exogenous agent and the great majority of periodic drinkers, especially so-called pathological drunkards, are really examples of short attacks of manic-depressive psychosis associated with alcoholism.

4. These fleeting attacks when mild in type and uncomplicated by alcoholism, are often mistaken for transitory mental conditions of other character, such as hysteria, psychic epilepsy, migraine, neurasthenia, etc.

5. These short attacks of manic-depressive psychosis may be associated by the patient with disturbances of bodily functions and interpreted as common physical ailments. These conditions are frequently regarded by the general practitioner as nervous dyspepsia, nervous heart, liver, and intestinal trouble, etc.

6. The recognition of the true character of these attacks is of the utmost importance, from the standpoint of treatment, as misdirected therapeusis will frequently intensify the underlying condition.

7. Important medicolegal questions frequently arise, for, during such attacks, patients may commit overt acts, such as assault, crimes of sexual character, attempted suicide, and even homicide.

CONSERVATION WORK AS APPLIED TO LIFE INSURANCE.*

By FRANKLIN C. WELLS, M.D.,

NEW YORK.

MEDICAL DIRECTOR OF THE EQUITABLE LIFE ASSURANCE SOCIETY.

If a life is of sufficient worth to an insurance company to assume it as a risk, it is fair to suppose that there is also an interest in the prolongation of that life. The present physical soundness of a subject seeking insurance is important, but the prospect that he will continue sound through a given number of years, is equally important. While actuarially we deal with classes, fundamentally we are dealing with individuals—if the individuals are healthy and so continue, the "classes" will be safe.

The history of medicine is replete with changes which have been occurring from earliest times.

Once little was known of the causation of disease; all that was sought for was some nostrum or method that would effect a cure. The idea of prevention was unknown, and although the same microbes and bacterium were in activity and in evidence, in those days, as now, it was the Pasteur School in France, and the School of Koch in Germany which gave to the scientific world the new idea, so tremendous and far-reaching in its effects, that there were specific causes for the diseases that were attacking men and animals. This idea was that a germ or microbe could reproduce itself, but that it might be destroyed or annihilated before

*Read at twenty-sixth annual meeting of the Association of Life Insurance Medical Directors of America, Oct. 15, 1915.

manifesting its attendant symptoms and results in the human organism.

Metchnikoff foresaw this era when he gave expression to the view that "the microorganisms inhabiting our bodies have set going there a 'poison factory,' which cuts short our existence by secreting poisons that penetrate all of our tissues, injure our most precious organs, the arteries, brain, liver, and kidneys. Man balked of his full term of life, feels himself unhappy and is ready to accept any solution to the problem of gaining happiness and health." If then man is balked or deprived of his full term of life, the problem confronting him is not alone concerning the output, product, or resulting effects of the "poison factory," but the regulation, and closure of it before it does its work, with attention on the "in-put" as well as on the "out-put."

It is easier to retain health than to regain it, and the gauge of any civilization is the standard it sets for the health and morals of its people, and the effort it puts forth to surround them with sanitary safeguards, and health-prolonging measures. No phase of this question is more important than the prevention of the so-called degenerative diseases, manifesting themselves at middle life and affecting the period of the greatest productivity.

For years the industrial system in this country seemed to bend its energies to the efficiency of the corporation. Then followed a period of amalgamation of the corporation for greater profit and efficiency. To-day we are entering up an era where the corporation, and the industrial and commercial world are beginning to realize that efficiency in its truest sense must begin with the conservation of the health and strength of the individual, and they are placing a higher estimate upon the value of the human machine, realizing that a man is greater, than a mill, the producer more important than the product, and that what injures the man will injure the machinery.

In all of this the life insurance companies may well have a share, in endeavoring to conserve and prolong the lives of those with whom they come most closely into relationship, and through them those dependent upon them.

What protects the breadwinner, will protect the breadconsumer, what safeguards the home, will likewise safeguard those under its roof. Measures intended to prolong the life of the provider of income, education and life's necessities, must also benefit those immediately dependent thereupon.

But from a more personal and even selfish viewpoint, the prolongation of the life of the individual policyholder, will add revenue to the company itself. Dimes thus expended may return in dollars to its tills.

In the case of a company which pays $20,000,000 a year in death losses, the prolongation of the life of each policyholder for one year beyond its present duration would have the following annual financial effect: The company would save one year's interest on $20,000,000, which at 4½ per cent. amounts to $900,000. One additional year's premiums would be paid in each case, which we can consider after deducting a year's dividends and commissions, as averaging $25 per thousand and amounting to $500,000 for the year. We, therefore, see that the total annual savings would be approximately $1,400,000. This sum is 7 per cent. of the company's gross mortality loss, or from 10 to 15 per cent. of the company's net mortality loss. This percentage (10 to 15) is more significant, as the net mortality loss shows the money paid out in excess of the reserves already accumulated on the policies involved. Looking at it from another point of view, the saving effected would probably equal one-third to one-half the gain from loading of participating premiums over expenses. All of this may be termed commercial selfishness, but if so it is an enlightened selfishness for it benefits "him who gives, as well as him who receives."

Some life insurance companies are beginning to realize this fact, and are placing in operation, and within the reach of the policyholder, means and measures for the early detection of disease, and pointing out a warning that the "poison factory" in the body is working overtime, and that the wheels should be slowed down or stopped. In all of this the company that I have the honor to be associated with is having a modest part, and endeavoring to contribute its portion to this end.

In July, 1914, we placed before our body of policyholders the opportunity, accompanied with an invitation, to avail themselves of a free medical examination, for the purpose of detecting and bringing to light any impairment or insidious physical impairment, not openly manifest. This examination was made without prejudice to the insurance record of the party applying, and the papers were entirely destroyed after a certain length of time.

We have been studying the problem, as well as feeling our way, and up to a recent date had accumulated records of 2032 full health examinations and 1178 (urinary only) examinations, the latter form consisting of a certain number of questions bearing on the health record, and a careful laboratory examination of the urine.

While these figures are not large, they furnish an interesting as well as instructive study. In observing the following tables, showing the relative frequency of impaired and unimpaired risks, it must be considered that many, and perhaps the majority of these policyholders who availed themselves of a full physical examination, did so because they felt that their health was not of the very best, or, at least, were suspicious of some physical impairment. This is, no doubt, the explanation of the high percentage of impaired lives.

The following table of full health examinations is interesting as showing somewhat the distribution by ages of impairments as follows:

	Ages to 29		30 to 39		40 to 49		50 to 59		60 and Over		All Ages	
Impairments noted by examiner	132	62%	312	65%	415	66%	300	70%	242	86%	1401	69%
Ailment noted by insured only	34	16%	106	22%	130	20%	84	20%	26	9%	380	19%
No impairments noted	47	22%	61	13%	88	14%	42	10%	13	5%	251	12%
	213	100%	479	100%	633	100%	426	100%	281	100%	2032	100%

As might be assumed, the highest ratio (22 per cent.) of unimpaired risks is among the youngest, the lowest ratio (5 per cent.) among those of 60 years old or older. Likewise, among the young it is to be found the lowest ratio of impaired risks (62 per cent.) as against 86 per cent for those 60 years old or older. From 16 to 26 per cent. of the policyholders put certain impairments in their ex-

amination blanks which medical examiner did not consider serious enough to note.

Relative to the nature of the impairments and to their number, we have listed the cases in accordance with the most serious ones that were found. Excluding the 76 insured who were 70 years old or older, we found that the most serious impairment affected the

Circulatory system in	493 cases or	24%
Genito-urinary system in	410 cases or	20%
Pulmonary system in	79 cases or	4%
Digestive system in	133 cases or	7%
Nervous system in	83 cases or	4%
Miscellaneous	127 cases or	6%
Entirely without impairments	251 cases or	12%
Minor impairments of little or no importance*	380 cases or	19%
Old age cases (70 to 85 years old)	76 cases or	4%
	2032	100%

*Such as occasional headaches, poor eyesight, slight indigestion, occasional dizziness, etc., etc.

In the majority of cases the impaired condition is caused not by one, but by several ailments of importance.

Regarding the 798 examinations, without impairments, 522 policyholders mentioned other impairments of more or less seriousness, as the blanks which the insured fill out ask many questions.

While all of this is an experimental state, it nevertheless goes to show the frequency of impairments in adult life—and during the "insurance age"—and instances might be cited to show the apparent beneficial result to those who by our examination have had their attention called to the necessity for immediate medical attenton and received benefit thereby.

These few suggestions are offered merely to direct attention to a subject that I believe will more and more receive consideration and form a part of legitimate life insurance work.

METASTATIC CARCINOMA OF THE BRAIN WITH UNUSUAL OCULAR SYMPTOMS.

CLINICAL HISTORY AND AUTOPSY REPORT OF A CASE.

BY SAMUEL HORTON BROWN, M.D.,

PHILADELPHIA.

IN the latter part of March, 1915, a patient was referred to me by Dr. N. S. McDowell of Philadelphia, on account of an intractable corneal ulcer. The patient had but recently come under his observation, and response to ordinary treatment being delayed, he preferred the patient having special attention. Accordingly she came under my care, and ultimately was seen in conjunction with Dr. Frederick Krauss in the latter's service at the Episcopal Hospital, Philadelphia.

The patient (No. 5,100—1914-1915) was a woman, fifty-eight years of age, a native of Germany, white in color, married, and engaged in the ordinary household duties. Her immediate trouble was an ulcer in the right eye. This had existed for several months, and according to the patient's statement had followed an operation on the side of the head for the relief of intractable neuralgia on that side.

Leaving the past medical history for future elaboration we examined the right eye and found several features of unusual interest. The conjunctiva of the lids and globe was intensively congested and a pinkish zone surrounded the cornea. Almost the entire cornea with the exception of a peripheral ring was involved by a process of infiltration that rendered it a dirty white color and densely opaque. The surface epithelium was wrinkled, but fluorescin failed to stain any denuded areas. The lower half of the cornea seemed to represent the remains of a previous sloughing ulcer. No view of the fundus was possible. The conjunctiva, the lids, the globe, and the entire cornea were anesthetic. There was very little discharge from the eye, but the condition of the lids caused such as there was to accumulate, requiring constant attention. The patient had been using atropine (grains 4 to the ounce) twice a day, but the pupil was only semidilated. A 5 per cent. dionin solution was being used twice a day for the relief of the pain in the eye, which pain was paroxysmal in character. There was no vision in this (the right) eye. The patient gave a history of double vision before the operation, and, of course, before the sloughing ulcer made its appearance.

Examination of the extraocular muscles of the affected eye showed orbicularis movement normal, levator palpebræ movement lost, all the recti movements lost, and the oblique movements lost. There was anesthesia of the skin of the right side of the face. The tongue turned to the right when protruded, and there were impaired taste and ordinary sensation on the right side of the tongue. Hearing was practically normal.

The left eye was normal in every particular until within a few days of dissolution. All movements were intact and the vision was five-sixths.

The patient was decidedly uncomfortable with this constantly exposed right eye, and it required continued attention to prevent accumulation of the discharge, slight as it was, and consequent infection. This attention was productive of far better results than anticipated, and while the ocular movements were not restored nor the cornea cleared the eye was brought into a comparatively comfortable condition free from discharge and annoyance. She left the city in pursuit of an occupation at the seashore (still having the pain in the side of her face), but returned in the early part of August, 1915, with some symptoms referred to the nose and throat, very much emaciated, and rather jaundiced, although her original color was of this nature, complaining of pain in the right side of the face, but worse in character than before. She was brought into the hospital a few days later in a semi-comatose condition with symptoms resembling meningitis, and died within a week after her admission. At this time there was pronounced exophthalmos of the right eye. The left eye showed blurring of the edges of the nerve, obliteration of the cup, and pronounced venous congestion (August 17, 1915). The history which follows seemed to indicate a metastatic growth in the brain, which diagnosis was confirmed at autopsy. The past medical history throws considerable light on the condition.

For several years the patient had been under the observation of Dr. Laura Chapin for various complaints, but who, on account of an increase in abdominal symptoms, had referred her (May 6, 1913) to Dr. Barton Cooke Hirst, who performed an exploratory laparotomy upon her (May 20, 1913) and found the intestines matted together by carcinoma. Nothing further was done at this operation except to close the opening in the abdomen. The patient was found to have also a large uterine fibroid. What happened to the fibroid is a matter of conjecture. Dr. Hirst's notes record nothing further concerning it, and the autopsy report makes no comment of it, although every detail of the uterus is noted.

In December (about December 8), 1913, the patient came under the observation of Dr. George E. Pfahler of Philadelphia on account of the increasing severity of the abdominal symptoms. Pain had become very great, requiring morphine frequently, and there was obstinate constipation. The entire abdomen was tender and there was general rigidity, and one could feel masses everywhere, according to the statement of Dr. Pfahler in a personal communication to the writer. The treatment was of an intensive sort and resulted in burning of the skin severely in several places.

On June 17, 1914, six months later, Dr. B. C. Hirst again examined the patient and reported that there was nothing left of the original condition except a very small mobile mass on the left side. A small sinus had meanwhile formed in the abdominal wall which Dr. Hirst seemed to regard as beneficial in allowing drainage. Several other surgeons, at Dr. Pfahler's request, examined the patient about this time, and with the exception of "a slight firmness" in the left iliac region found no evidence of malignant disease as originally noted by Dr. Hirst. This sinus, already referred to, developed above the pubes and was regarded by Dr. Pfahler as incidental to the discharge of necrotic tumor tissue, and was not connected with the bowel. The autopsy record notes the ultimate course of the sinus.

Dr. Pfahler noted at this time that the patient complained of the slow healing of the *x*-ray burns, and of more pain, especially in the head, than the condition seemed to warrant, and fearing metastasis to the brain

made an *x*-ray examination of the head August, 1914, but found nothing abnormal.

November 6, 1914, she was admitted to the surgical wards of the Episcopal Hospital, from the records of which department the following history is obtained:

The family history showed that the mother died of paralysis, the father died of heart disease, one brother died of tuberculosis, and grandmother died of cancer of the breast. Patient was married and divorced. Husband living and well. Patient has one son, living and well, but had had four miscarriages. The patient had had neuritis of the legs four years previously. Nine years ago she had a uterine-suspension operation performed. Menopause had taken place at fifty-two years of age and she had had no subsequent bleeding or discharge. Reference was made to the operation one year ago by Dr. Hirst in which "a tumor of the bowel was removed." Eleven months prior to admission she stated that she began to have *x*-ray treatment for cancer of the stomach which was followed by great improvement although attended with erythema and vesication.

One year previous to admission she noticed a numbness and dull pain under her right eye, which was accompanied by some pain and paralysis of the face, eyelids, and mouth. Gradually these symptoms extended to include the whole right side of the face, scalp, and mouth, and simlarly the inside of the mouth and tongue, presumably on the right side. There was also paresthesia on the right side of the face. Previous to the face conditions she had had pain in the right eye for several months. She had no headaches in the ordinary sense of the word; although she was constipated the appetite was good. There was no edema or pain in the feet. Cough was absent. Loss of weight to the extent of ten pounds within a year was noted.

On admission (notes by Dr. Robertson, resident physician) the patient appeared to be well-nourished, well-developed, and of a large frame. There was no adenopathy. The skin was warm, dry, and wrinkled. Tortuosity and some sclerosis of the peripheral arteries were present, but there was no cough, cyanosis, or dyspnea.

Concerning the head, the notes record iron-gray hair, ptosis of the right upper eyelid, slight weakness of the right side of the face, and almost complete anesthesia of the right half of the head, face, nose, mouth, and chin. The tongue and lower jaw deviated to the right very much. There was considerable deafness in the right ear. The tongue was slightly coated on the dorsum. The teeth were in good condition. No view of the throat was obtained.

Gross examination of the neck was negative in its results. Examination of the lungs was also negative. The breasts were normal. The heart was normal in position, although there was slight enlargement to the left. The sounds were of good quality, regular, and no murmurs were heard. The second aortic sound was accentuated.

External examination of the abdomen revealed the presence of old burns with scars and granulations on both flanks. A mid-line scar corresponding to the site of a previous abdominal incision, at the end of which was a sinus discharging pinkish, purulent material with a foul odor, was observed. The abdomen was flabby and there was some tenderness in the lower left quadrant. The spleen and liver were not palpable.

Examination of the extremities showed no weakness or paralysis or disturbances of sensation. Reflexes were present, but were sluggish. Station and gait were normal.

The patient's principal complaint was pain in the right side of the head which was constant but with acute exacerbations from time to time. Contact with draughts of air, and the taking of food increased the severity of the pain. Lacrimation of the right eye was observed. The patient never complained of headache in the ordinary sense of the word, of nausea, or of vomiting. Until after operation she had no disturbance of vision. A few days after admission she complained of toothache in the lower left first molar tooth. The *x*-ray burns and the sinus previously noted made slow progress toward recovery. One week after admission she was examined by Dr. John L. Bromley of the Eye Service who reported the eyes to be normal, and by Dr. Charles C. Biedert of the Ear, Nose, and Throat Service, who likewise reported these several structures and their adjacent sinuses to be normal. A day or two later, the teeth were examined by Dr. Cameron of the Dental Service, who found an alveolar abscess connected with the upper left first bicuspid tooth and a carious lower second left molar. On the right side of the mouth there was nothing abnormal. A bridge was being worn below that might possibly have been causing some pain.

The interne in his notes at this time observed no intermissions in the pain, but also recorded a confusing observation that there was some pain and diplopia in the left eye. The burns on the left side of the abdomen were almost well at this time, but otherwise the patient had made little or no progress.

Twelve days after admission it was noted that the patient was beginning to become despondent. In accordance with the desire to eliminate every etiological factor, she was given 0.6 gram of neosalvarsan intravenously in order to secure a provocative Wassermann reaction. Lumbar puncture was performed and about ten cubic centimeters of clear fluid were removed. Both serum and spinal-fluid Wassermann tests were later reported as negative in their results.

During the following week vomiting and pain were prominent symptoms unrelieved by a host of therapeutic agents, including galvanic current, codeine, mercury, iodides, aconitine ointment, hot water bags, freezing with ethyl chloride, and morphine. The latter caused temporary mental unbalance.

A few days later (February 27, 1914), attempts were made by the use of the Levy-Voudouin cannula to inject 90 per cent. alcohol into the superior maxillary and mandibular branches of the right trigeminal nerve at their points of exit from the foramen rotundum and foramen ovale. The first division of the nerve was injected at the supraorbital foramen. Apparently these attempts were successful since two days later the record reads that there was present almost complete anesthesia of the parts supplied by the right trigeminal nerve, although less perfect over the lower lip, chin, and lower cheek. The patient, however, noticed no lessening of the pain. There were present also some swelling of the right side of the face and slight ecchymosis of the right upper eyelid. The *x*-ray burn on the left side of the abdomen was noted as healed at this time.

The face appeared "puffy" for several days following this operation. Headache was present as was also the pain in the face. The blood pressure at this time was 193 systolic, and less than thirty ounces of urine were voided in twenty-four hours. The lungs were clear but the heart was hypertrophied. Nephritis was present at this time.

On December 7, 1914, excision of the Gasserian ganglion was performed by Dr. H. C. Deaver at the Episcopal Hospital. A horseshoe incision was made beginning one inch in front and ending one inch behind the external auditory canal. This flap together with the periosteum, temporal fascia, and muscle was then turned down. With a hand drill a hole was then trephined in the skull just above the external auditory canal, and the opening in the skull was enlarged with rongeur forceps. The petrous portion of the temporal bone was then exposed. Bleeding from the diploë was free and was controlled by Horsley's bone wax. By means of a dural separator and the finger, the dura was stripped from the base of the brain. The brain was then held up by the bent handle of a spoon. The middle meningeal artery was not seen. The Gasserian ganglion was located and by means of a blunt hook and long blunt dissectors was freed, and the three branches and root were isolated. With a long hemostat the ganglion was held while it was excised by long uterine scissors. The ophthalmic division with the corresponding portion of the ganglion was then removed. The brain was replaced. The flap of skin, fascia, and muscle was sutured with silkworm gut interrupted sutures. The right eye was irrigated with boric acid solution and covered with an eyepad and a shield. Dressings were then applied to the wound in the side of the head.

On the day following the operation, the patient noted a feeling of numbness and tingling in the right side of the face and on the succeeding day acknowledged that the pain was less. Four days after operation it was observed that the cornea was anesthetic and there was slight injection of the conjunctival vessels. The convalescence from the operation was good, with the exception of irritability and occasional delirium, but subjectively the patient was no better than before the operation.

Nine days after operation, Dr. Bromley noted that the right cornea was anesthetic, motion of the lids was good with the exception of slight ptosis of the right upper eyelid. The right eye could be moved upwards but motion in all other directions was absent. A linear

ulcer was present at the lower central portion of the cornea. Dr. Bromley expressed the opinion that there had been some injury to the motor nerves of the eye in the course of the operation.

From this time on the symptoms appeared to be centered about the right eye. In the first place the patient refused from time to time to permit the nurse to irrigate the eye. It must have been painful to her to have it done. Edema of the lids and conjunctiva appeared and became progressively worse. The conjunctival vessels became injected. The original corneal ulcer became larger and a second superficial ulcer appeared on the cornea. With the progress of the edema and corneal ulcers, the lids failed to cover the eye perfectly and the condition was further aggravated. While the general condition of the patient was good, mental irritability was more or less constantly present and delusions of persecution were in evidence at times.

While the edema of the conjunctiva became less and the cornea became clearer, and, altogether, the patient was in a much better condition within a few days, she felt that she was not receiving satisfactory attention and signed the release so that she could go home, but changed her mind, after notifying the office of the hospital, and decided to remain. At this time the chief conditions consisted of an almost healed *x*-ray burn on the right side of the abdomen (December 22, 1914), fistula at the lower end of a scar in the abdominal wall, and anesthesia of the right side of the face with cloudiness of the cornea of the right eye with disturbances of motility of the globe.

The condition of the cornea of the right eye fluctuated considerably during the following three weeks. At first the cornea was steamy with radiating streaks in it; the pupil was partially and irregularly dilated, and the anterior chamber appeared shallow. At the end of one week improvement was noted, but a slight linear corneal ulcer was observed in the left eye. The latter lasted four or five days. The condition of the right eye remained stationary for about one week and then marked improvement followed, so that by January 16, 1915, the notes showed the right eye to have very little edema and congestion of the conjunctiva, and a hazy cornea but not in the process of ulceration or inflammation.

During this last three weeks, the patient improved mentally as well as physically and had very little pain. Some of the healed *x*-ray burns broke down but promptly healed up again. January 16, 1915, the patient was discharged as a house case, in very good condition.

After a period of treatment at the Out-patient Department she came under my observation about April 1, 1915, through the reference of Dr. N. S. McDowell as previously noted, with the condition as already given in detail. She was seen at St. Christopher's Hospital for Children but for convenience she was again referred to the Episcopal Hospital, but this time to the service of my very good friend Dr. Frederick Krauss, with whom she was studied in detail.

At this time there was a decided trophic ulcer of the cornea involving almost the entire cornea, suggesting impending sloughing of the cornea. Under the influence of a supporting bandage closing the eyes continuously, the free irrigation of all secretion, and the instillation of atropine, holocain, and dionin, the immediate distress of the eye was ameliorated, but even after three months of the closest attention, the cornea was still intensely clouded. At no time was it possible to get any view of the fundus in the right eye. The left eye was normal in every particular.

During the patient's attendance at the Out-Patient Department, she seemed to be in fairly good health although she did complain of more or less continuous painful sensations over the right side of the face unrelieved by any medication. The use of the local remedies mentioned served to restore the cornea and conjunctiva to comparative health, although exacerbations of the ulcerative condition were quite frequent. Despite the condition the patient's general health remained about the same and she left the city to seek employment in Atlantic City in June, 1915.

In the early part of August she was observed in the Nose and Throat Clinic, very much emaciated and cachectic, and in a most despondent frame of mind. Shortly afterwards she was taken suddenly ill at home and lapsed into a semicomatose condition. Her original physician, Doctor Chapin, had her returned to the Episcopal Hospital immediately (August 17, 1915). The history given to the interne, on admission, was that for two or more weeks previously the patient had had impairment of hearing, taste, and smell. For the last three days prior to admission she had had severe headache. Two days before admission she was found unconscious on the floor, since which time she had been in coma with loss of speech and incontinence of urine. She was constipated but had had no vomiting, convulsions, or demonstrable paralyses.

Examination on admission showed semicoma with stertorous breathing resembling the Cheyne-Stokes type. The ears and nose were negative. The tongue and pharynx were covered with mucus and crusts. The tongue deviated to the right when an attempt was made to move it although the patient was unable to protrude it. Attempts at speech resulted in irregular rolling of the tongue, but articulate sounds were incapable of production. The ocular examination showed right total ophthalmoplegia, exophthalmos, marked conjunctival injection, no view of fundus on account of corneal scar. In the left eye, venous engorgement of the fundus was marked, the veins being especially tortuous. Blurring of the optic disk and complete effacement of the physiological cup were noted.

Examination of the heart, lungs, and abdomen revealed no new condition. Examination of the extremities showed little or no movement of the left leg and arm, the leg being held flexed and somewhat rigid. The arm was nearly, although not quite, flaccid. Knee jerks were absent and there was no ankle-clonus or Babinski sign. The neck was stiff and Kernig's sign was present on both sides.

The temperature on admission was 102.2° but dropped to 99.2° within a few days and slight improvement was noted. It then abruptly rose to 103° with pulse 128, and respirations 24, and within twelve hours the patient had developed edema of the lungs, which edema ended in dissolution on the fifth day of her sojourn in the hospital. The patient came to the autopsy table with the provisional diagnosis of Metastatic Carcinoma of the Brain secondary to Carcinoma of some of the Abdominal Viscera, and Nephritis. The autopsy performed by Drs. Dibble and Kirchner under the supervision of Dr. C. Y. White, pathologist of the Episcopal Hospital, showed the following to be present: Ptosis of the transverse colon and hernia; chronic interstitial nephritis; traumatic ventral hernia; adenocarcinoma (medullary) of the sigmoid; metastatic carcinoma of the peritoneum; metastatic carcinoma (medullary) of the right frontal lobe of the brain.

The detailed findings showed the heart and lungs to be normal except for slight dilatation of the heart and slight anthracosis, hypostatic congestion, and edema in the lower lobes of the lungs.

The abdominal examination showed many old and firm adhesions causing distortion of the viscera. The transverse colon had dropped far down, a loop of it occupying what appeared to be a large ventral hernia. The stomach, duodenum, jejunum, and ileum were normal, except for adhesions distorting the small intestines. There were no adhesions about the cecum or appendix. There was a hard mass in one side of the wall of the sigmoid about 5x4x2 cm. The peritoneum was glistening and thickened. The liver was bound down by many adhesions, especially to the diaphragm and its resistance to cutting was greater than normal. The kidneys showed the presence of chronic interstitial nephritis. The pelvic viscera were massed together by adhesions but were apparently normal. The bladder was congested and studded with tiny miliary white points. The spleen was normal.

The various glands of the lymphatic system, such as the cervical, the axillary, the bronchial, the mediastinal, the mesenteric, and the retroperitoneal glands, showed no demonstrable lesions, and were recorded as normal. The osseous and cartilaginous systems were normal. The adrenals were unaltered. The thymus and thyroid presented no lesions. The mammary glands were apparently healthy. The nose and throat were normal from the outside. There was marked exophthalmos with corneal opacity of the right eye. There was a scab over part of a scar in the right iliac region apparently from some remote operation together with numerous scars over the abdominal wall. There was also an apparent diastasis of the rectus abdominis muscles about 10 cm., below the umbilicus.

Examination of the brain showed the dura to be transparent, its inner surface being smooth and glistening. The arachnoid was transparent and moist. The cerebrum was normal except for a lesion noted below, as were also the cerebellum, pons, and medulla.

In commenting upon these findings the pathologists observe: "Palpating from within the abdomen there was a circular opening between the recti muscles below the umbilicus, with sharply defined edges all around and about 10 cm. in diameter. This was underlying an old surgical scar in the abdomen. The opening led into a cavity of some size, lined with peritoneum and contained a large loop of the transverse colon which was not adherent. The intestines were all matted together in the lower and left side of the abdomen. The transverse colon was ptosed and had drawn down with it the omentum. In the descending colon were some sharply punched out ulcerations with abrupt margins and blackened base. The largest of these was about one centimeter in diameter. In one side of the wall of the sigmoid flexure was a hard irregular mass with a whitish color on cross section, and quite firm. At the base of the right frontal lobe of the brain was a friable fungating mass of tissue about 5x4x3 cm., in size and of very irregular shape. It was rather resistant to the knife and seemed to contain some 'gristly' particles. It had eroded the cribriform plate of the ethmoid, entering the upper part of the nose. It had also destroyed the configuration of the sella turcica by erosion and appeared to have invaded the orbit. There was much blood about this growth. In color it was pinkish yellow. There was no distinct capsule."

In analyzing the several points in connection with this case, it seems in order to emphasize the intermittent character of the symptoms in carcinoma of the abdominal viscera, since this case illustrates this clinical feature very well. There were intervals of comparative comfort. As in this case the disease does not always progress to destruction of the organs involved, and dissolution often comes from some intercurrent disease. Without the history and the presence of the *x*-ray burns it is doubtful if there would have been any reference to abdominal symptoms at the time after the case came under our observation.

It is also well worth noting that the symptoms referable to the face were complained of prior to the operation on the Gasserian ganglion, and consisted of numbness and dull pain under the right eye, pain and paralysis of the face, eyelids, and mouth, and paresthesia of the right side of the face. These and the other head and face symptoms would indicate conditions directly referable to the fifth nerve, and afford a justification for the subsequent removal of the ganglion.

It should be borne in mind that the patient's principal complaint was continuous pain with paroxysmal attacks of still more acute pain in the right side of the face over the distribution of the fifth nerve, unrelieved by medication, and it was for the immediate relief of this that the surgical procedures were instituted, the other symptoms being too vague to definitely diagnose and localize the suspected intracranial neoplasm.

After the removal of the ganglion, symptoms of involvement of nerves other than the fifth became pronounced. These were regarded by some of the observers as incidental to the manipulation of the structures in the course of the operation. Going back to the symptoms complained of one year before admission, and on admission, and returning to the post-mortem notes regarding the location of the metastatic growth in the brain with its destruction of its bony resting place, we are inclined to regard the removal of the ganglion as connected only with the ultimate destruction of sensation and trophic influences of the fifth nerve and as having very little to do with the other nerve palsies. Movement upwards was retained for a long while after the operation, but when she came under our observation, several months later, it was entirely lost. If due to the operation it should have been lost immediately.

The occurrence of pain in the side of the face after all pathways of sensory impulses had been destroyed permits considerable discussion on the subject of referred pain, to take part in which is beyond the scope of this paper.

Death did not occur as the result of either the primary or secondary growth, directly. It was undoubtedly due to interstitial nephritis. The coma was uremic in character, the urinary findings indicated renal changes, the left eyeground showed intense congestion of the fundus, edema and swelling of the disk, not formerly present, and the post-mortem showed kidney disease and edema of the lungs. This is in accord with the universal observations among general practitioners that the subjects of carcinoma succumb to kidney changes.

This detailed history is given, not with the idea of commenting upon the treatment, which I consider not open to comment or criticism, but with the purpose of contributing something to the etiology and symptomatology of brain tumors in general and to metastatic growths in particular, especially when situated anteriorly.

1901 Mount Vernon Street.

TUBERCULIN AS AN AID IN SURGICAL TUBERCULOSIS.*

By CHARLES BERNARD BURKE, M.D.,

ATLANTIC, IOWA.

In presenting a paper before this society upon the subject which I have chosen, I recognize full well that there is no specific remedy for tuberculosis; none which corresponds to antitoxin in diphtheria, 606 in syphilis, or quinine in malaria; yet there are certain remedies which, while they have enjoyed only limited trial by the profession, are found to have a specific action when used with certain surgical operations upon tuberculous tissues.

While Koch's old tuberculin failed to produce the beneficial results expected, and was in consequence discredited and the use of the remedy fell into disrepute, we believe that the failures of the first epoch were, without exception, the result of improper dosage and methods employed in the administration of the remedy. For that reason no one is justified, on the grounds of the experience of 1891, in passing adverse judgment upon the remedy. On the contrary, it is important that the remedy be extensively tried anew and especially as an aid in rebellious surgical tuberculosis, for which indications, we believe it occupies an important status.

That the value of this remedy has not been recognized is due to a misconception of what should be expected of such remedies. We well know that antitoxin is the anchor of hope in diphtheria; yet we also know that, to be efficacious, it must be used early; and all things being equal, the prognosis varies with the early or late administration. In surgery we know that the knife is a specific for many diseases; yet it has its limitations, and after a certain point in the disease has been reached this specific fails. While the field of these specifics is limited, yet their value is in no way impaired by the fact of this limitation. In the case of tuberculosis, however, the profession has not been satisfied with a remedy of limited value. The profession has been unreasonable, especially in surgical tuberculosis, for it has demanded that the remedy, to be of value, must be one that not only cures the disease, but also removes the results of disease, namely, the

*Read before the Botany Valley Medical Society, Avoca, Ia., Aug. 27, 1915.

necrotic tissues. Such demands are unfair and unreasonable, and if the same test were applied to other remedies, how many would stand? In tuberculosis we must demand no more of a remedy, and no less, than in other diseases. As followers of the healing art, we should seize upon everything that will help, and apply it to the advantage of the patient, not discard even the smallest thing that will aid us to combat disease.

I have found tuberculin to be a splendid aid when used in conjunction with surgery. It has been especially useful in those tuberculous cases that seem to defy all other treatment; those undesirable cases, in connection with which we sit up nights praying that the patients may see fit to change doctors, for we are ashamed to see them continue to place their confidence in us after we have played our last card, and without results. In this class of patients, I have found that, while the results of tuberculin is very slow, they are gratifying.

We have until quite recently used the new tuberculin or T. R. exclusively, beginning with a 1/10,000 mg. and carefully increasing the dosage to 1/600 mg., watching the patient closely for even the slightest reaction. We agree, however, with Dr. Schorer when he says in regard to the various preparations, "no one of the more ordinary preparations of tuberculin possesses any material advantage over the others." Bandelier and Roepke have wisely said, "tuberculin can exert no curative action on the secondary purulent processes caused by the streptococcus, pneumococcus, influenza bacillus, and other bacteria, which, as a rule, occur only in advanced cases with cavity formation; there is rather the possibility that the unavoidably severe reactions may, in such cases, afford opportunity for extension of the secondary infection and lead to a worse condition. But these are the only cases in which direct harm may be caused by tuberculin. Hence, we strongly deprecate the attempt being made in this class of cases, which are already hopeless."

Tuberculin acts especially well in most cases of tuberculosis of the bones, glands, and skin. In all these cases, however, the treatment should be well regulated and supplemented by all of the treatment usually given to patients having tuberculosis. Dr. E. H. Schorer lays down the following contraindications to its use: marked fever, hemoptysis, heart lesions, and marked emaciation. It is well to examine the patient for other foci before using tuberculin in surgical cases, lest we light up a focus we are not looking for and thus cause ourselves a little embarrassment and the patient considerable pain and discomfort.

Tuberculin is a valuable addition to our surgical armamentarium in that it promotes healthy granulation and permanent healing; it relieves the patient from toxic symptoms, making him more buoyant especially in the advanced chronic cases, and the good results are decidedly more permanent. I think we can say, without fear of contradiction, that tuberculin can do no harm when given in the doses mentioned above, and when the patient is carefully watched for a reaction, and as soon as even a slight reaction occurs, the remedy is discontinued for at least ten days.

The so-called clinical method is the procedure of choice in the administration of tuberculin, and its aims are simply to avoid any reaction by commencing with a very small dose and gradually increasing it without producing any general reaction.

Drs. Hawes and Floyed classify the forms of tuberculosis in regard to the effects of tuberculin as follows:

1. *Forms of Tuberculous Disease which React Favorably to Tuberculin.*—(*a*) Incipient pulmonary tuberculosis, especially in the closed stage in children; (*b*) Chronic advanced pulmonary tuberculosis; (*c*) Tuberculous adenitis in children; (*d*) Tuberculosis of the eye; (e) Genitourinary tuberculosis.

2. *Forms of Tuberculosis which React Less Favorably to Tuberculin.*—(*a*) Febrile advancing pulmonary tuberculosis: (*b*) Tuberculous adenitis in the adult; (*c*) Bone tuberculosis; (*d*) Lupus; (*e*) Tuberculosis of the larynx.

Dr. A. P. Francine has aptly said, "While expert opinion generally favors the therapeutic use of tuberculin within certain limitations, the fact must be strongly emphasized that it is a powerfully acting remedy, a toxin of great potency, and it may do harm as well as good. It should be employed with the greatest watchfulness and skill, in properly selected cases." It should be remembered that tuberculin is not a serum, that it is the diametric opposite of an antitoxin, and should not be confused with serums which claim to be antitoxins for tuberculosis, but which have thus far failed to merit this name.

Some of the varied and numerous constitutional symptoms, which may occur during a positive reaction after the injection of tuberculin are: Indisposition, pain, aches in head, back, limbs, or other parts of the body, anorexia, nausea, vomiting, diarrhea, chills, sweats, dizziness, weakness, dyspnea, insomnia; local signs at and around the area of injection, such as redness, tenderness, swelling, impairment of function, increased muscular and tendinous spasm, deformity, an increased local temperature; while tuberculous skin lesions will exhibit signs of engorgement, pain, tenderness, swelling, and increased local temperature.

The above reactions may follow the injection of tuberculin, no matter how pure the product may be.

The surgical treatment does not necessitate the complete removal of all the tissues that may be infected with the tubercule bacillus, but only the portions that are indefinitely necrotic need be removed, since from the case reports that follow, as well as the observations of others, one may conclude that healing of extensive tuberculous processes may occur under tuberculin injections without the surgical removal of all the diseased tissues.

It should, of course, be emphasized that the removal of such necrotic tissues is of great importance, and that the tuberculin treatment is essentially an auxiliary measure to be used with such surgical treatment as is indicated in a given case. It has been shown by Dr. Carl G. Swenson that the new tuberculin or T. R. may be injected with safety and without Wright's opsonic index control, if we commence with a dose of a 1/10,000 mg. and gradually increase it up to 1/600 mg. and not repeat the dose until ten days have elapsed.

Dr. Porter says that since he has abandoned the opsonic method of Wright, he is using the Packard method which consists in beginning with small doses, small enough to produce no reaction, and slowly increasing in those cases which are neither doing well nor hopelessly badly, but those in which the patient has good resistance but needs a little assistance to tip the scale toward recovery. Even in such cases, the first sign of a reaction is an indication to discontinue the remedy for a while.

Tuberculin is a most valuable remedy in treating surgical tuberculosis where the lesion is limited, in which the disease is pursuing a quiet, slow course without pronounced feverish conditions and not much general disturbance, also in non-febrile cases with a fairly good appetite, in which the process is slow and chronic, and in cases that seem stationary; but, in all cases of advanced pulmonary tuberculosis with laryngeal, renal, or intestinal complications and high fever, showing general disturbance, the use of tuberculin is strictly contra-indicated; cachetic individuals and prostrated persons also are unsuited for tuberculin treatment.

It should be given cautiously to incipient active tuberculous patients, because even in the small doses it may react very vigorously, whereas large doses in old tuberculous cases may not cause any reaction at all.

This paper was prompted by the results in the following cases, which are here cited to illustrate some of the clinical results obtained by its use.

CASE I.—Mr. J. P. came to me for treatment June 5, 1915. He gave the following history: During the last two years he has had three operations upon his neck for what was called "an abscess of the neck." The operations failed to relieve him and the condition gradually became worse until all the cervical glands became involved, and some underwent caseous degeneration. Th cite of incision, when I first saw him, was a sinus exuding a seropurulent discharge, and the tissues over tumor were greatly indurated and imparted to the palpating fingers, a sensation of board-like rigidity. We made sections of some of the tissues removed at this time and also made smears of the discharge on blood serum. The sections showed the tubercle, but we were unable to find the bacillus from the cultures.

We took him to Mercy Hospital and did a radical operation for the removal of the cervical glands, but we were unable to remove all the infected tissues because we would not have enough flap to close our wound if we did. We did, however, remove all the old scars. After operation the wound apparently healed kindly, but after two weeks' time it began to break down, and he was put on tuberculin injections. After the third injection the wound began to clear up and healthy granulations appeared. The induration gradually disappeared and the wound has healed, as you may see, in a kindly and permanent way. He had in all, six injections.

CASE II.—Mr. O. W. received an injury to knee on one of the seats in the Opera House while passing out of the rows of seats. He paid no attention to his injury, which was apparently of a trivial nature. A few months later his knee began to swell and continued to remain stiff and swollen for months. He went to Rochester, where he received injections of Beck's bismuth paste, but for financial reasons he had to return home and his knee continued to swell and became painful and stiff. Later it was necessary to remove his leg above the knee because his entire knee-joint became honeycombed as a result of his disease. Following his operation the flaps healed kindly for a time, and then broke down and discharged a serous fluid. He was put on tuberculin and after two months' treatment he had perfect union of flaps, and they have remained healed to this day. His operation was performed in 1910.

CASE III.—Mr. J. S. was operated on for what was termed an empyema. The incision refused to heal. Two years after operation he came to me to see if I could heal his side. He was taken to Mercy Hospital, where his pleural cavity on one side was filled with Beck's bismuth paste, the scare tissue removed, and the wound brought in apposition. He also received tuberculin, and after two months on the tuberculin treatment the wound healed and has remained healed to this date. The diagnosis was verified by the Koch's old tuberculin cutaneous test, by both the Von Pirquet and Moro methods.

CASE IV.—Mr. N. G. had his right testicle removed for tuberculous epididymitis and orchitis. The testicle was almost completely destroyed by his disease. The incision healed by first intention but three weeks later broke down and began to discharge a serous fluid. He was put on tuberculin and it promptly healed and has remained healed. The diagnosis was verified by the Moro test.

INDICANURIA AND THE SULPHATES.

BY JOHN C. WARBRICK, M.D.,

CHICAGO.

IT may be said the metabolism of the body could not be carried on in any way without the constant intake of food material, of a mixed variety, and water from time to time; these are necessary to supply activity, energy, and proper functioning of all the tissues, on account of the waste that goes on regularly from day to day, requiring repair.

It would thus seem that the chlorides, phosphates, and sulphates also are more or less under the control of the body metabolism as governed by diet.

As the chlorides then form almost an integral part of the body so the same may be said of the sulphates, both being under the control of the tissue metabolism, for it is known that either of them can be increased or decreased according to certain conditions, such as by the amount and kind of food, exercise, water drinking, and the free movements of the bowels.

In the urine, as is known, are preformed sulphates of sodium, potassium, calcium, and magnesium, while the fluid also contains sulphur in the form of sulphocyanides, hyposulphites, and sulphuretted hydrogen.

Sulphur is taken into the body in the protein as in meat and eggs, also as sulphates of sodium and potassium, while it is eliminated as sulphates of indol, phenol, and skatol, the odor of the feces being due to these. Along with cresol this group of four is termed the aromatic series.

They are the ethereal, conjugate, or organic sulphates and are supposed to be formed during putrefaction occurring in the intestinal canal, especially of protein food material.

More or less putrefaction must take place in the intestinal canal as a result of digestion and so much waste matter must always be thrown off for the health of the body. When this is delayed and if much putrefaction occurs, indican is more likely to form.

Indol is supposed to be the basis of indican, and it is said to occur especially from the putrefaction caused by the action of bacteria on protein. This is oxidized to indoxyl and is excreted, and combined with sulphuric acid and sodium or potassium, as indoxyl sodium sulphate or indoxyl potassium sulphate, which is called indican. Where there is much consumption of protein food along with suboxidation of the tissues the amount of sulphates is likely to be much increased and the amount of indican also on account of the delayed metabolism of the tissues. Where there is loss of nervous tonicity and the tissues are devitalized indican is more likely to form.

In most cases the sulphates would almost seem to be more stable than the chlorides, although they seldom if ever reach to as high a figure except it may be in some peculiar instances, the tendency being in most cases for the sulphates to be low.

In some cases where the chlorides are low from suboxidation of the tissues and delayed metabolism the sulphates may be found at a high figure; the amount of indican being also increased.

In order to find out the relation of the indican present to the total amount of sulphates twenty-five specimens of urine were examined quantitatively for sulphates and indican. From these examinations one would think the sulphates had a considerable part in the formation of indican, for it was found that with a small amount of sulphates the amount of indican was high in many cases. Out of twenty-five cases of urine examined in not one single instance was the amount of sulphates beyond the normal daily maximum figure, but mostly below it. In only one instance was the sulphate index beyond the normal daily minimum figure.

	Color	Sp. Gravity	Sulphates	Indican
1.	Light yellow	1002	½: 8	0
2.	Reddish yellow	1006	¼: 4	0
3.	Yellowish red	1010	¼: 4	10
4.	Reddish yellow	1012	½: 8	0
5.	Reddish yellow	1018	¼: 4	0
6.	Yellowish red	1020	¾:11	10
7.	Yellow	1020	1 :15.5	15
8.	Yellowish red	1020	½: 8	15
9.	Reddish yellow	1022	½: 8	Ft. trace
10.	Reddish yellow	1022	½: 8	0
11.	Yellowish red	1024	1 :15.5	6
12.	Yellowish red	1024	1 :15.5	5
13.	Yellowish red	1024	1 :15.5	10
14.	Yellowish red	1024	1 :15.5	20
15.	Yellowish red	1024	1 :15.5	5
16.	Yellowish red	1026	1 :15.5	10
17.	Yellowish red	1026	1 :15.5	20
18.	Yellowish red	1026	2 :31	10
19.	Yellowish red	1028	1 :15.5	3
20.	Yellowish red	1028	1 :15.5	10
21.	Yellowish red	1028	1 :15.5	20
22.	Yellowish red	1030	1 :15.5	15
23.	Yellowish red	1030	1 :15.5	5
24.	Yellowish red	1034	1 :15.5	5
25.	Yellowish red	1036	1 :15.5	11

In about 140 out of 320 cases where the urine was examined for the amount of sulphates the figure was at 1—15.5 below both the normal daily minimum and maximum amount, thus showing the tendency is for them to be low.

THE PHYSICAL VERSUS THE PSYCHICAL IN PSYCHIATRY.

LOOKING at them from a broad viewpoint the ranks of the alienists seem at present to be split into two main parties. On the one hand we have those who believe that mental disease, leaving out of the discussion of course such cases as primary defect and organic cerebral disease, is always due to physical causes and on the other hand those who hold that the so-called functional psychoses are due to psychical causes.

Let us take for example a disorder which is not only the most common, but about which there is the most difference of opinion, dementia precox. Those who favor the psychical etiology point out that dementia precox presents at first a clinical picture which suggests an acute physical disorder. They quote the onset which is often sudden, attended perhaps by a convulsion, headache, vertigo, and confusion. When fully established, especially in the catatonic variety, there are numerous physical signs. Especial stress is laid on these by the English school formerly led by Stoddard who now seems to have gone over to the psychoanalysts. These signs include pupillary anomalies, fine tremors of the hands and face, exaggerated reflexes, hyperactivity of some secretions and diminution of others, gastrointestinal disturbances, loss of weight, dermographia, etc.

The more progressive exponents of the physical theory are inclined toward an endocrinous etiology of the functional psychoses. They believe that the symptoms, both physical and mental, shown in these disorders, merely represent altered functional activities of the cerebral cells, due to a toxemia resulting from an anomaly of an internal secretion, possibly that of the thymus gland. The internal secretions of the sex glands are naturally looked upon with suspicion because of the facts that these diseases are most likely to begin at puberty and are often associated with disturbances of the sexual sense. Among the foremost representatives of the physical theory in this country must be mentioned Southard, Bayard Holmes, and Ernest.

The psychiatrists who believe that back of psychic events we must look for psychic causes hold that the disorders of metabolism which we often observe in the psychoses in question as well as the degenerative changes frequently seen in the cortical cells post mortem are due to derangements of the psychic apparatus. They quote in support of this view, aside from their ingenious psychology, that we often see cases which exhibit no physical or physiological signs whatever and frequently in the autopsy room brains fail to show any definite pathological changes whatever although the patient may have had precox for many years. They believe, to put it as succinctly as possible, that the vital energy, or libido, may be arrested at any point in its development and remain fixed there or turned backward upon itself and come to a standstill at an infantile level. The precox according to their psychology, suffers from a splitting of the field of consciousness, or schizophrenia, very similar to the hysteric. This school of psychiatry in this country numbers among its adherents White, Jelliffe, Brill, Emerson, Putnam, Kempf, and Lind.

When specialists disagree, to paraphrase the old saying, it is not for general practitioners to say which is right, and perhaps just now it does not make a great deal of difference. The encouraging feature of the whole situation is that we are abandoning our old attitude toward the mentally diseased, that is, that they are social pariahs whom we must shut up behind bars for the balance of their days, and are beginning to look upon them as human beings very like ourselves, but suffering from disorders just as real and predetermined in their way as any other disease. We are commencing to realize that it is our duty to search for the causes of mental trouble that we may find the remedy, and if the searching parties after truth diverge widely in their quest and each proclaims that it alone has the one true light it is probable that they are all right to some extent and that a fusion of all the stray illuminants picked up here and there will one day bring modern daylight into the medievalism of mental science.

IMMUNIZATION IN EXPERIMENTAL GLYCOSURIA.

THIS is a subject that deals with a field of investigation as yet largely unexplored. That metabolic disorders can be influenced by procedures similar to those employed in combating the invasion of the body by certain infections is a revelation that offers results of eminently practical value in clinical medicine. The conception of immunization against glycosuria first suggested itself to Andrea Ferrannini in 1907, and since that time he and his pupils have studied various aspects of the problem. The results of this work are reported by Ferrannini in *La Riforma Medica*, September 18, 1915.

It has been definitely established that there are certain substances that tend to combat or inhibit the glycosuria produced by the injection into the body of certain other substances. Thus pancreatic extract combats the glycosuria caused by suprarenal extract; methylene blue, that caused by phloridzin, and also glutaric or paratartaric acid, that caused by phloridzin. To the above group of antagonisms there are added by Ferrannini and his associates the following: Methylene blue inhibits the glycosuria evoked by morphine; santonin com-

bats the glycosuria produced by morphine or phloridzin, and an extract of the salivary glands counteracts the glycosuria produced by phloridzin or morphine and, to a lesser extent, that produced by suprarenal extract. Three different sets of facts have since been established: (1) The injection into an animal of suprarenal extract, phloridzin, or morphine in doses sufficient to produce glycosuria imparts to the blood serum of this animal the property, when injected into another animal of the same species, of preventing the development of glycosuria following the injection of suprarenal extract, phloridzin, or morphine. (2) This immunization against the development of glycosuria is also acquired by the blood serum if the animal is injected with the substances that tend to inhibit the corresponding glycosuria; these substances (pancreatic extract, methylene blue, etc.) being administered at such long intervals as to remove all doubt as to the possibility that the accumulation of these substances in the body is the real factor in the inhibition of the glycosuria rather than the immunizing power of the blood serum. (3) The development of glycosuria is also prevented if the animal is injected with the blood serum of another animal of the same species which has already received injections of a so-called "antiglycosuric system," namely, a glycosuria-producing substance in conjunction with its antagonist, *e.g.* suprarenal extract with pancreatic extract, morphine with methylene blue, or phloridzin with methylene blue.

As regards the specificity of the immunizing properties of the blood that are acquired under the conditions detailed above, the fact has been established that these properties are not absolutely specific. They are only relatively so. Thus a blood serum obtained from an animal injected with phloridzin will immunize another animal of the same species against the glycosuria produced by phloridzin, but also to a lesser extent against the glycosuria produced by suprarenal extract, etc. The biological mechanism concerned in the above immunizing properties consists in certain changes wrought in the metabolism of glucose rather than in an inhibition of the excretion of glucose by way of the kidneys.

Another set of facts of practical importance have been revealed. Just as there may be developed an immunity with respect to experimental glycosuria so also there may be evoked a true glycosuria anaphylaxis. Thus, if small doses of a glycosuria-producing substance are injected repeatedly at long intervals during a certain period of time, and if there is then injected a larger dose, this last will evoke glycosuria even though the amount injected is less than the amount usually required to produce glycosuria in the same animal. The identical anaphylactic phenomenon is observed if, following the preliminary stage of small doses, there is injected the corresponding mate in the so-called "antiglycosuric system."

The significance of the above investigations cannot be overestimated. From the viewpoint of the larger problem of metabolism in general, they show that the processes of bodily chemistry are governed by the same laws as those that control the defence against invading microorganisms; or, to express this fact in a more logical order, these investigations show that the chemical processes of defense are identical with the larger processes of metabolism. But there is a more immediate practical value in the results of the researches conducted by Ferrannini and his associates. There is opened up a new avenue of attack in the treatment of the various types of pathological glycosuria. The possibility of a serum treatment of diabetes would seem therefore to be a remote vision.

THE COMMUNICABILITY OF LEPROSY.

THERE has been a great deal of criticism of the health officers of certain States for their summary treatment of leper suspects, and while we think much of the criticism is deserved, it might be well to note that in spite of the conclusions of the Leper Congress that leprosy is not contagious, there are certain elements with regard to certain phases of this affection which make one feel that he is in the presence of a very mysterious disease. The true method of origin or communication of leprosy is not known. Until about the middle of the last century the disease was practically unknown in Hawaii, where it is now so extremely prevalent, it having been imported by the Chinese coolie settlers. In addition to the natives the number of foreigners who have lived a considerable time in Hawaii and who have contracted the disease is quite large. Leprophobia is not merely confined to places where the disease is only heard of with all the natural exaggerations of hearsay evidence, but is engendered even among those in whom familiarity would be expected to breed contempt. The belief that the disease is with difficulty transmitted is born of an ignorance of the circumstances necessary to be present for communication. Thus syphilis is a highly communicable disease, but it is nevertheless transmitted under certain conditions of contact. It is fairly well established that leprosy is not hereditary. Children of lepers who are immediately, within the first few weeks, removed from contact with their parents remain free from the disease, and the likelihood of children remaining free depends upon the promptness of their removal from the leprous environment.

As regards its etiology, there is still some uncertainty. While the bacillus of leprosy is universally considered to be the causative agent, we are yet dealing with the least identified or differentiated bacterial entity. It is merely known that this bacillus is an acid-fast bacillus found abundantly in the discharges and in the tissues of the leprous. As an acid-fast bacillus it is in the same class with the smegma and tubercle bacilli. But while this retention of the stain has some relation to its protoplasmic composition, it is not a sufficiently pertinent characteristic. The tubercle bacillus is rather easily cultivated, but its presence as a causative agent is especially demonstrated by the fact that it fulfils the Koch postulate—isolation, cultivation in pure culture, animal inoculation and reproduction of the disease, and recovery in pure culture. On the other hand, previous to Clegg's cultivation of

the bacillus in symbiosis with the ameba, the lepra bacillus was impossible of cultivation. Clegg succeeds, moreover, only in the cultivation of an acid-fast bacillus under these conditions, but he cannot reproduce the disease in animals or otherwise carry out Koch's postulate, which would stamp this acid-fast bacillus as the specific agent. The one authentic experiment in which a Hawaiian, a convict, was inoculated with a lepra culture, and who later contracted the disease, is not entirely convincing; first, because even one positive instance does not carry sufficient scientific certainty, and, second, because the experiment was carried on in a Hawaiian native already exposed to the disease from residence.

Likewise, the question of diagnosis adds to the already present difficulties. The best informed men have differed on the same case. In marked cases—in the later stages, when any damage from communication will already have been done—there is little trouble in the diagnosis. It is very often difficult to differentiate leprosy from syphilis, and there is, therefore, no discredit to the ancients if it is true that they confounded leprosy with syphilis and tuberculosis. Often, as between syphilis and leprosy, only the history of exposure gives a clue to the probable condition. It has even been frequently difficult to distinguish the leprous disturbances of sensation appearing in the early stages of the disease from the trophic disturbances of like character present in the later stages of syringomyelia.

Cases of leprosy have been found everywhere, and it becomes difficult to comment accurately on the general prevalence of this disease. Certain it is that there is a strong and growing impression that leprosy is more prevalent and more communicable than was previously supposed; yet this may be only the normal and to-be-expected swing of the pendulum, and the fact remains that the ready communicability of the disease is not proven. In any case the exaggerated leprophobia existing in the popular mind and fostered by some health officers is without basis in fact and may result in extreme cruelty in individual cases.

Conclusions Drawn from a Study of the Literature of Fractures.

In a recent editorial article we stated that the popularity of the Lane plate method of treating fractures of the long bones reached its zenith and began to wane about the time when the inlay bone-graft technique was being developed, and that this latter has now become the method of choice with perhaps the majority of American surgeons, particularly in the treatment of ununited fractures. Since this was written several articles on fractures which were read at the recent meeting of the American Surgical Association have been published. Among these is a paper by Thomas W. Huntington (*Annals of Surgery*, September, 1915) in which the relative merits of the metal plate and the autogenous bone-graft are discussed. The author's conclusions formed after a review of the literature of fractures for the last ten years are as follows: (1) The public demands, and is entitled to, better results from fracture treatment than have hitherto been obtained. (2) From 80 to 90 per cent. of long-bone fractures can be successfully treated by the closed method. (3) Conservative treatment exacts a high degree of skill and close attention to details. (4) Resort to the open method is of too frequent occurrence. (5) The least possible amount of foreign fixation material should be the rule. (6) Steel plates in the treatment of fractures are a menace from the standpoint of permanency. (7) The bone implant is the fixation material of choice. (8) Intramedullary splints are inferior to the autogenous bone implant. (9) Fixation material of whatever type is not to be relied upon for maintenance of alignment. (10) Cases of non-union and faulty union which come to secondary operation indicate indifferent methods of primary treatment. (11) Operative treatment of compound fractures should be withheld until the external wound healing is perfected. (12) Many joint fractures can be treated successfully only by the open method. (13) Normal contour and good function are closely related in the end results of all fractures.

False Broadbent Symptom.

In complete symphysis of the pericardium and in adhesion between the latter and the diaphragm there should be, according to Broadbent, a systolic retraction of the intercostal spaces between the tenth and twelfth ribs at a point about 6 cm. in front of the spine. In practice this behavior is seldom encountered, and it is also conceivable that other conditions than those already named can produce it. At a recent session of the Vienna Society for Internal Medicine and Pediatrics (*Berliner klinische Wochenschrift*, July 12) Ortner relates a case in which this symptom was present, but not in a high degree. There were, however, no evidences of pericardial adhesions, and the heart had normal mobility. There was a systolic apex impulse in the sixth interspace, the diaphragm was placed on a level with the twelfth dorsal vertebra and its respiratory excursion was very small. The patient had a pendulous abdomen and visceroptosis, and when these states were corrected the apex beat mounted to the fifth interspace, and the systolic retraction disappeared. The retraction is evidently connected with the low position of the diaphragm, as if the lung could not be inflated sufficiently to prevent the development of negative pressure in the thorax. This, however, does not explain why retraction occurs only at the area in question. This doubtless results because the expanding lung is insufficient to offset the slight systolic diminution in the size of the heart along with its forward movement. The patient's heart was hypertrophied as a result of mitral lesions of rheumatic origin, and he also had arteriosclerosis.

An Alleged Successful Treatment of Disease Carriers.

A successful treatment of disease carriers is possible in theory when the microorganisms are strictly localized in an accessible region, the criterion of success being the disappearance of the said organisms. In the case of diphtheria, simple sterilization of the upper air and food passages by local means has indeed been pronounced a failure in certain cases, and immunizing injections have been superadded; while as for cerebrospinal meningitis disinfection of the nasopharynx of suspects and convalescents cannot be regarded as necessarily con-

ferring protection to the community. This was the status of the subject before the outbreak of the present war, but in a communication before a military medical evening at Cologne last summer (*Deutsche medizinische Wochenschrift*, September 9), Küster claimed that an intensive local disinfection is alone able to jugulate an epidemic. Several cases of epidemic cerebrospinal meningitis having appeared in the fortress of Cologne, examination of the nasopharyngeal secretions showed that every other man was a carrier. A preparation which liberated chlorine was improvised and was inhaled in spray form, the exposure lasting a full hour, and the treatment being repeated on the two succeeding days. At the end of this period soldiers who had presented virulent microorganisms in the nasal and faucial secretions—meningococci, Klebs-Loeffler bacilli, and staphylococci—were pronounced sterile.

News of the Week.

Committee of American Physicians for the Aid of the Belgian Profession.—Dr. F. F. Simpson, M.D., treasurer, 7048 Jenkins Arcade Building, Pittsburgh, Pa., announces the receipt of the following contributions for the week ending December 11, 1915:

Buffalo Medical and Surgical League, Buffalo, N. Y.		$5.00
Washington County Medical Society, Calais, Me....		25.00
Previously reported receipts		7,873.84
Total receipts		$7,903.84
Previously reported disbursements:		
1,625 Standard boxes of food at $2.20...	$3,575.00	
1,274 Standard boxes of food at $2.30...	2,930.20	
353 Standard boxes of food at $2.28...	804.84	
Total disbursements		7,310.04
Balance		$593.80

Nurse Dies Abroad.—Miss Emma Duensing, head nurse of the first medical relief expedition to Germany of the American Physicians' Committee, who had been on duty at Oppeln, Silesia, Germany, for some months, died of septic poisoning on November 3. It is said that because of the great lack of rubber gloves the nurses in the military hospitals are improperly guarded from infection, and that through this lack Miss Duensing, who was considered one of the most efficient nurses of the German Hospital, New York, contracted the infection.

Drop in German Birth Rate.—The *Züricher Zeitung* recently published a dispatch from Berlin giving the official birth statistics in twenty-four of the principal towns in Germany from April to July, 1915, inclusive. The statistics show a decrease of 30 per cent. in the birth rate.

Hospital Ships Not Put to Improper Uses.—In view of the allegations made in Germany wireless press dispatches that British hospital ships were being put to improper use the hospital ship *Mauretania* was examined by American, Danish, and Swiss consuls, who absolved the British of the charge of bad faith. A declaration to the effect that there were neither combatants nor any war stores aboard was signed by the consuls.

Bequests to Charities.—By the will of the late Louise Cobb of Philadelphia, the sum of $700 is bequeathed to the Pennsylvania Hospital for the Insane.

By the will of the late Andrew Freedman of New York bequests of $5,000 each are made to Mount Sinai Hospital, the Montefiore Home, the Roosevelt Hospital, St. Vincent's Hospital, the Presbyterian Hospital, and St. Luke's Hospital. The residue of the estate, which will amount to several million dollars, is to be used for the erection and maintenance of a home, to be known as the Andrew Freedman Home, for aged persons, without regard to race, sex, or creed.

By the will of the late Henry A. Rogers of Philadelphia the sum of $4,000 is bequeathed to the Sanitarium Association for Children.

By the will of the late Emily M. Price of Philadelphia the sum of $10,000 is bequeathed to the Children's Hospital for the endowment of a free bed in memory of George M. R. Price.

By the will of the late Mary E. Harbeson of Philadelphia the sum of $5,000 is bequeathed to the Women's Homeopathic Hospital for the endowment of a free bed in memory of Estelle H. Biddle.

By the will of the late Maggie Greene of Philadelphia bequests are made as follows: $1,000 to the American Oncologic Hospital, $1,000 to the Kensington Dispensary for the Treatment of Tuberculosis, $700 to Temple University, $700 to the Samaritan Hospital, $700 to St. Christopher's Hospital.

Teaching Food Values.—The Bureau of Food Supply of the Association for Improving the Condition of the Poor has recently undertaken in New York a public campaign to popularize the results gained by studies of food values and economics. The first exhibit, called "From the Farm to the Cooker," was opened early in December at the Tompkins Square Branch of the Public Library. It includes an educational display designed to explain clearly the nutrition values of most of the staple food products and to demonstrate the proper selection of foods and the handling of them in a sanitary and economical manner. The lecturer in charge of the display will give advice as to the preparation of food, etc. Similar exhibits will be opened later in other places throughout the city.

Instruction for Food Inspectors.—In order to perfect the food inspectors of the New York City Department of Health in the details of their work, the director of the department's Bureau of Food and Drugs has organized a course of lectures, conferences, and demonstrations, dealing with the various aspects of pure food work. These lectures are in the nature of a post-graduate course and each detail of the work will be presented by experts.

Standard Diets in Health Department Hospitals.—In order to establish standard dietary methods in the hospital service of the Department of Health, the director of the Bureau of Hospitals some time ago appointed a "menu committee," composed of the resident physicians, the supervising nurses, and the dietitian of the department's hospitals, the committee being instructed that the quality of the food in the new menus must not be below that of the food in use at the time. The dietary methods recommended by this committee were introduced in January, 1915, with complete satisfaction. The quality of the food has been above criticism and a saving also has been effected, amounting in nine months to $10,000 in the hospitals for contagious diseases alone. This saving has been accomplished in three ways: 1, by diminishing the amount of high-priced food (meat) in the various dietaries and substituting other food stuffs equally nutritious and less expensive; 2, by eliminating waste in the preparation of the food, this being made possible by the use of standard menus; and, 3, by giving the employees the kind of food they wanted and thus reducing plate waste.

Salvarsan Promised.—It is again announced that the French and British Governments have agreed, at the request of the United States, to allow the shipment of a six months' supply of salvarsan and neosalvarsan from Rotterdam to this country. It is hoped that a sufficient supply to meet all demands will be here within the next three or four weeks or earlier. There will be no increase in price of the drug. An effort will be made, it is said, to induce the patentees to allow the product to be made in this country, Dr. Baketel having given assurances to the British Government to this effect. Physicians are, in the meanwhile, warned against spurious products, said to be made in Canada, which have been offered for sale in New York, Chicago, and other large cities.

To Censor Noise.—The Police Commissioner of New York has undertaken to reduce the unnecessary noises in the city, and has issued a general order to the force holding the members responsible for the strict enforcement of all the laws and ordinances designed to lessen the din.

New Wing to Woman's Hospital.—At the sixtieth annual meeting of the Woman's Hospital, New York, on December 9, the new Thompson Pathological Building, forming the west wing, was formally opened. The building has been erected through the generosity of Mrs. Frederick F. Thompson, chairman of the Ladies' Board of the hospital, at a cost of about $150,000, including the equipment. It is of buff brick, to conform with the main building, and is eight stories high. The street floor is devoted to the out-patient department, the second contains the electrotherapeutic ward, and the third rooms for private patients; the fourth and fifth are given over to pathological laboratories, and the upper floors contain operating rooms, etc. A solarium has been built on the roof. It was announced at the meeting that during the past year 2,500 patients had been treated in the hospital and 3,728 operations performed.

Guggenheim Memorial.—Work is soon to be begun on an addition to the Mount Sinai Hospital, New York, to be known as the Guggenheim Memorial. The entire cost of construction, estimated at $500,000, will be defrayed by the sons of the late Mr. and Mrs. Meyer Guggenheim. The new building will occupy about half of a city block and will be practically a complete hospital in itself, containing 100 private rooms, operating room, laboratories, kitchens, offices, reception rooms, etc. The roof will be fitted up as an outdoor ward. There will be also a children's corridor, shut off from the remainder of the building so that the noise made by convalescent children will not disturb the other patients; and guest rooms, for the use of those who wish to stay with patients in the hospital will be another innovation.

Civil Service Examinations in Philadelphia.—The Philadelphia Civil Service Commission announces that examinations will be held on the dates specified for the purpose of filling the following positions in the Department of Health and Charities:

January 12.—Druggist and First Assistant Apothecary, at a salary of $600.

January 13.—Assistant in pathological and bacteriological laboratory, at a salary of $720.

January 17.—City Nurse (woman), at a salary of $900.

January 18.—Resident Physician (open to residents of Pennsylvania), at a salary of $600-$900.

January 19.—Assistant Bacteriologist, at a salary of $1,400-$1,500; First Assistant Bacteriologist, at a salary of $2,000; Fourth Assistant Bacteriologist, at a salary of $1,000.

In order to obtain application blanks for the above examinations, candidates must call in person at the office of the Civil Service Commission, Room 875, City Hall, Philadelphia.

Personals.—Dr. JOHN S. BILLINGS has been advanced to the office of Deputy Commissioner of Health of New York City. He will continue the direction of the Bureau of Preventable Diseases, of which he has for some time had control, and will also take charge of the work of dividing the city into health districts.

Dr. CHARLES B. PENROSE has been appointed a member of the Fairmount Park Commission of Philadelphia.

Dr. EMIL MAYER of New New was elected an honorary member of the Philadelphia Laryngological Society at a meeting of the Society held on December 7.

Dr. ARTHUR DEAN BEVAN of Chicago was elected president of the Society of Clinical Surgery at the meeting in Washington on November 26 and 27.

Trudeau Sanatorium.—In honor of its founder, the late Dr. Edward Livingston Trudeau, the name of the Adirondack Cottage Sanatorium, Trudeau, Saranac Lake, N. Y., has been changed to Trudeau Sanatorium.

Harvey Society Lecture.—Prof. Florence R. Sabin of Johns Hopkins University will deliver the fourth in the present series of Harvey Lectures, at the Academy of Medicine, New York, on December 18, 1915. The subject of the lecture will be: "The Method of Growth of the Lymphatic System."

Medical Department of Columbia University.—On the recommendation of the Medical Faculty the trustees of Columbia University voted on December 6 to change the title of the medical department to "The College of Physicians and Surgeons of Columbia University."

The Society for the Advancement of Clinical Study announces a continuation of its bureau of information relative to surgical and medical clinics held in New York City. A bulletin board is maintained for this purpose at the Academy of Medicine, 17 West Forty-third street, in charge of a competent attendant who will be on duty from 9 to 12 in the morning and 2 to 6 o'clock in the afternoon to answer inquiries. The special telephone number is 3375 Bryant. The clinics held at the various hospitals are posted on a special circular of information, which will be mailed to outsiders at 50 cents per week to cover postage, etc. The bulletin board maintained at the academy also contains the daily clinics as well as those held at stated hours in various hospitals. The facilities thus offered afford to visiting physicians who are interested in observing special operations and operators or clinicians, an opportunity to obtain the desired end with the least trouble. The success of the enterprise is shown by the constantly increasing number of inquirers who make use of these facilities, and it is hoped by this means the large and unexcelled opportunities for medical research and observation afforded by New York City will be made more accessible to those who may desire to make use of them.

Hospital Examinations.—The Joint Examining Board of the New York Hospitals, including the Hudson Street Hospital, the Roosevelt Hospital, St. Luke's Hospital, and the Knickerbocker Hos-

pital, will hold a competitive examination of candidates for interneships in these hospitals. The date of the examination has not yet been selected, but notice of it will be mailed to the candidates not less than one week before the examination. Application blanks and full information concerning the character of the examination and the number and nature of the positions to be filled may be obtained from Dr. Charles L. Gibson, chairman of the Examining Board, care of the New York Hospital, 8 West Sixteenth street, New York. All applications must be in the hands of the committee by December 31, 1915.

Opticians' League of the State of New York.—The annual meeting of this society was held on November 17 at the Hotel Lorraine, New York. The meeting was called to order by the retiring president, Mr. E. B. Meyrowitz, and after the reading of the minutes and reports officers for the ensuing year were elected as follows: *President*, Charles L. Pilger; *Vice-President*, J. B. Hoecker; *Treasurer*, Henry C. Badgley; *Secretary*, Edward L. Seip; *Director for Three Years*, Theodore Obrig. With a view to obtaining a larger attendance at the meetings and of adding materially to the membership list it has been arranged to provide during the winter a series of lectures on optics in its fundamentals, upon ethics, and upon efficiency both for the employer and the employee. The annual banquet will be held in February.

Medical Association of the Greater City of New York.—The fifteenth annual special meeting was held at the Imperial in Brooklyn on December 6. An address was made by the president, Dr. Thomas S. Southworth, and the following scientific programme was presented: "The Surgical Treatment of Bronchiectasis," by Dr. Earl H. Mayne; "Percussion Technique and Theory," by Dr. Bernhard A. Fedde. Dr. Robert E. Coughlin, chairman for the Borough of Brooklyn, presided. This association was incorporated in 1899 as a society which should represent the best elements in the medical profession in all the five boroughs of the enlarged city. During each year, from October to June, eight meetings are held in Manhattan and one in each of the other four boroughs.

Obituary Notes.—Dr. Ap Morgan Vance of Louisville, Ky., a graduate of the University of Louisville, Medical Department, in 1878, a member of the American Medical Association, the Kentucky State Medical Association, the Jefferson County Medical Society, the American Association of Obstetricians and Gynecologists, and the Southern Surgical and Gynecological Association, and a fellow of the American College of Surgeons, died at his home on December 9, aged 61 years.

Dr. Asa P. Reed of Dorchester, Mass, a graduate of the Tufts College Medical School, Boston, in 1895, died suddenly at his home on December 2, aged 58 years.

Dr. Thomas Jefferson Upshaw of St. Louis, Mo., a graduate of the American Medical College, St. Louis, in 1890, died at the home of his son in St. Louis, after a short illness, on November 22, aged 71 years.

Dr. Henry McKee Tucker of Raleigh, N. C., a graduate of the University of Maryland, School of Medicine, Baltimore, in 1899, professor of gynecology in the Leonard School of Medicine, Raleigh, and a member of the Medical Society of the State of North Carolina, the Wake County Medical Society, and the Raleigh Academy of Medicine, died at the Rex Hospital, Raleigh, after a brief illness from meningitis, on November 24, aged 39 years.

Dr. George B. Bristol of Middlebury, Conn., a graduate of the Yale University Medical Department, New Haven, in 1892, died at his home after a long illness, on December 1, aged 79 years.

Dr. James Irving Cawley, Register of Wills of Bucks County, died at Springtown, Pa., on December 11, at the age of 62 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1877.

Obituary.

ABRAM ALEXANDER SMITH, M.D., LL.D.

New York.

Dr. A. Alexander Smith of this city died suddenly on December 13 of disease of the heart. He was born at Wantage, N. J., March 25, 1847. He received his collegiate education at Lafayette College, and was graduated in medicine from the Bellevue Hospital Medical College in 1871. After serving a term on the house staff of Bellevue Hospital he began practice in this city and continued in the same with but slight interruptions up to the day of his death, a period of over 43 years. He was successively attending physician to the Demilt Dispensary, attending physician and surgeon to the Woman's Hospital, and consulting physician to Columbus Hospital, the Hospital for Ruptured and Crippled, and the Minturn Hospital. In 1875 he was appointed adjunct lecturer on clinical medicine in the Bellevue Hospital Medical College and had ever since been a member of the faculty, being at the time of his death professor of the principles and practice of medicine and clinical medicine at the University and Bellevue Hospital Medical College.

Dr. Smith was a member of the American Medical Association, of the Association of American Physicians, the National Association for the Study and Prevention of Tuberculosis, the American Climatological Association, the Practitioners' Society of New York, and the New York Academy of Medicine, being a trustee of the latter at the time of his death.

KENNETH WILLIAM MILLICAN, M.R.C.S.

London, England.

Dr. Kenneth W. Millican, formerly editor of the *St. Louis Medical Review* and also at various times connected in an editorial capacity with the *Journal of the American Medical Association* and the *New York Medical Journal*, and for several years past assistant editor of the *Lancet*, died last week in London of heart disease. He was born in England in 1853 and received his medical education at the University of Cambridge and St. Mary's Hospital, London.

Dr. Millican was well known and beloved by numbers of the medical journalists of this country, where most of his professional life was passed. At the recent meeting of the American Medical Editors' Association in this city, announcement of his serious illness was made and resolutions of sympathy were passed. Besides being an editor of great ability and a writer of graceful prose, Dr. Millican had the mind and heart of a poet and had written much pleasing verse, two volumes of which had been published.

Special Article.

PATHOGENICITY OF STREET DUST.

REPORT BY THE PUBLIC HEALTH COMMITTEE OF THE NEW YORK ACADEMY OF MEDICINE.*

THE active interest of the Public Health Committee of the New York Academy of Medicine in the problems involved in efficient street cleaning led to the preparation of this study on the pathogenicity of street dust. In a report prepared by the Committee over a year ago and submitted to Mr. John T. Fetherston, Commissioner of the Department of Street Cleaning of New York City, the Committee maintained that a system of street cleaning can not be called satisfactory which does not eliminate gross street dust and which employs dry sweeping methods. At the joint conferences with the Commissioner the relation of dust to public health, as well as the relative importance of dust and spray or cough infections, were discussed and, at the request of the Commissioner, a study was undertaken by the Committee to bring together the existing evidence concerning the causative relation of street dust to the various forms of disease, in order that the Department of Street Cleaning might have a scientific basis for its efforts to promote street cleanliness, in a sufficiently simple form to appeal to the general public.

This report is limited to a consideration of the single phenomenon of dust infection and does not attempt to discuss the relative importance of this source of infection to that derived from other sources.

SUMMARY.

I. Numerous bacteriological examinations made in this city, as well as elsewhere, show that street dust contains a variety of living pathogenic organisms such as tubercle bacilli and various types of streptococci which are recognized as causative agents of many respiratory and other diseases.

II. Although there exist only a very few positive instances where the production of disease can be traced directly to pathogenic bacteria present in dust, yet the fact that these organisms are found in appreciable numbers in street dust and are inhaled or ingested, establishes a presumption that street dust may at times be a cause of disease.

III. Studies with reference to the incidence of certain respiratory diseases show that persons free from exposure to city dust are less liable to suffer from these diseases than those so exposed.

IV. Dust has, for a long time, been universally recognized as an injurious mechanical irritant and as a cause of lowered bodily resistance, and one of the first prerequisites of public health has been the elimination of dust as far as possible.

V. Dry sweeping should be entirely abandoned. An adequate system of street flushing should be introduced in street cleaning procedures of our cities and effort should be made to apply all available means to make the streets as free from dust as possible.

*The Report was prepared by Dr. Thomas W. Hastings and approved by the Committee: Dr. Charles L. Dana, chairman; Dr. James Alex. Miller, secretary; Drs. T. Passmore Berens, Nathan E. Brill, Robert J. Carlisle, Floyd M. Crandall, G. A. Friedman, Lewis F. Frissell, Arpad G. Gerster, S. S. Goldwater, Thomas W. Hastings, L. Emmett Holt, Abraham Jacobi, Howard Lilienthal, William G. MacCallum, Bernard Sachs, W. Gilman Thompson, Philip Van Ingen, Karl M. Vogel, George B. Wallace, E. H. Lewinski-Corwin, executive secretary.

PREVALENCE OF PATHOGENIC BACTERIA IN DUST.

The relation of dust to public health has been looked upon as settled since the early work of Pfluegge and his pupils, and as late as 1915 these statements have not been controverted or questioned, but have been embodied in manuals and text books on Public Hygiene (vide Czaplewski).

Among the early reports on dust in relation to public health are a few in English; of these some relate to conditions in New York City in the early '80's and '90's. Included in the latter are those of Griscom, 1850; Report by a Citizen's Committee of New York, 1878; T. M. Prudden (book), 1891; Hinsdale, 1896; Firth, 1899. The later reports referring to conditions about and near New York are those of Bergey, 1903; Hessler, 1904; Corbusier, 1905; LaFetra in the Archives of Pediatrics, 1906; Soper, 1907; Bryant, 1908; Chapin, 1914; Winslow, 1910.

Articles by Miquel in 1889 and by Prudden in 1891 are worth quoting in detail. In relation to pulmonary affections, the source of living germs which form such an important part of dust in cities, is discussed by Prudden, who states on page 89 that " * * * * * Moist air not charged with bacteria, or charged with bacteria singly or in masses, or attached to other gross particles of dust must be dried before bacteria can be suspended in the air as disseminable dust." The method of determining bacteria in dust by cultural tests (page 11), is given in detail, from which one would comprehend that later methods of investigation have been no more thorough than the earlier methods given by Prudden.*

Prudden reported that in dry weather the germs in the dust out of doors are supposed to be in great numbers, but this is not usually the case; but where streets are often filthy and improperly cleaned, as in New York City, where the dust whirls around the corners of buildings forming air eddies, microorganisms are often present in very large numbers, so that one is apt to encounter "germ-showers." When the ground is wet and the air currents are moderate the number of germs is diminished. Prudden stated (1890) that in the dust clouds which sweep along the ill-kept streets of the City of New York or are blown from the street-sweepers as they pass along the unwatered thoroughfares into the houses or over the unwary passerby, the number of germs to the liter is startling. After 5 minutes' exposure of the 3¾-inch culture plate, clean dust gave 10 to 35 colonies to the liter, blowing dust from 214 to 941, and, following the street-sweeper, 5810 colonies. These statements merely corroborate the work done on the continent two or three years previously by Miquel.

RELATION OF DUST TO BACTERIAL INVASION.

It must be considered that the invasion of the tissues or organs by living pathogenic bacteria implies the possibility and probability of disease. It is a matter of common experience that street dust acts as an irritant to the eyes and produces a lower resistance in the tissues under the lids. This locus of lowered resistance is more liable to infection than under normal conditions. Dust laden with bacteria,

*Methods in fluid media, cultured after filtration through cotton, sand, sugar; plating on hard plates exposed on the surface, corresponding to the filtration method and plate exposure method of to-day. (These methods have no relation to the determination of colonies per cubic foot or cubic liter of air, as determined by Miquel.)

moreover, will find the proper conditions of moisture under the lids for bacterial development. This statement is unquestionable, and the fact is also well established that bacteria-free dust particles lodging in the ball of the eye frequently produce a traumatic irritation with subsequent secondary infection, resulting in disability and often permanent impairment of vision. From the eye conditions produced by dust, or dust irritation, one is led to distinguish the two types of dust referred to by Prudden as causing or being capable of causing affections or disease of the eye. Interpretated in the same phraseology of Prudden, they are the "germ-free" and "germ-laden" dust.

In addition to the self-evident eye conditions there are the results of inhalation of dust. These may be briefly summarized by quoting Prudden (page 42). "In spite of the safeguards with which the lungs are furnished a considerable number of particles of one kind or another lodge permanently in the lung tissue in situations where they will least interfere with the action of the lungs; yet they do harm by producing a lowered resistance in the lung and making individuals more liable to bronchial affections." Following the inhalation of bacteria-laden dust many bacteria do not grow in the human body, but Prudden states in reference to the tubercle bacillus that they may find conditions favorable for growth.

It is well known to-day that streptococci of various types are viable in a dry state in dust for undetermined periods of time which are long, from the nature of the case. Recent reports upon the wounded in France, and bacteriological studies in this country by Fuller and Armstrong, Thro, Winslow and Palmer, show that the dust from the soil and the mixed dust from cities may contain streptococci in sufficiently large numbers to cause infection. In certain soils, as in northern France, bacteria, such as tetanus bacillus, "gas bacillus" and streptococci are present. Recently it has been the practice in the large base hospitals on the continent to give prophylactic doses of "gas bacillus" and streptococcus vaccines as well as anti-tetanic serum. This is done for the purpose of fortifying cases against streptococci obtained from the soil (not necessarily soil contaminated with fecel material) which soil, and therefore dust, may contain pathogenic streptococci.

The possible relation of certain forms of streptococci to respiratory tract infections particularly, was first shown by Andrewes and Horder in 1906, and by Gordon in 1905. It is not only likely, but practically proven, that their *Streptococcus equinus* is the same as the *Streptococcus viridans*, or green-producing streptococcus, which is found so commonly in cases of tonsillitis, associated with rheumatic conditions and in forms of infective heart disease, in common colds and persistent cases of bronchitis. Numbers of these last cases have been thought for years to be due to the influenza bacillus.

To summarize briefly, it is not only the tubercle bacillus that is to be feared from the dust, as insisted upon by Prudden, but also in cities such as New York, the pathogenic streptococci as well.

Prudden states specifically (page 51) that inorganic dust when inhaled in large quantities may cause well-defined disease by persistent irritation, but only among those confined in narrow quarters under conditions such as obtain among mine-workers. A great deal of misery, if not positive disease, is caused by inhalation of dust, by persistent cases of protean catarrhs and also by irritation of the eyes. To quote Prudden (page 53) "If it were not for the few species of disease-producing bacteria, most people could afford to be indifferent as they are to dust." And, "If we could completely isolate disease-germ-bearing men and animals, such diseases could be completely stricken from the list of diseases, unless lighted up afresh by discharged material on walls, garments, or in the soil, or aerial dust."

There is no necessity for discussion on the production of infectious dust in cities; it is well known that expectoration by man, fecal material of animals, refuse sweepings into the streets from houses will contaminate dust that was originally bacteria-free. Prudden (page 75) says, "In out-of-door air in the country and also in streets kept decently clean there is little danger from dust. If dust clouds are encountered; if streets are not properly sprinkled before sweeping, by machine or hand; if street-cleaners are allowed to scatter clouds of dust, the chances of inhalation are proportionately increased.

The first satisfactory investigation in regard to the relation of dust by inhalation to disease is reported by Merkel. He studied the relation of different kinds of dust to the prevalence of emphysema, chronic bronchitis, pneumonia, and pulmonary tuberculosis. For purposes of comparison he studied these in relation to exposure to (*a*) Metallic dust; (*b*) Mineral dust, (*c*) Vegetable dust, (*d*) Animal dust, (*e*) Mixed dust, (*f*) No exposure to dust. Street-cleaners, laborers, etc., came under the category of those exposed to mixed dust. Those living in the country or in well-cleaned streets came under the head of "No exposure to dust" and the incidence of the four diseases considered was considerably less than in those exposed to any of the dusts specified from (*a*) to (*e*). The same facts were determined by Miquel for Paris and other cities in France. For New York City no such investigation has been made and no figures are obtainable.

PATHOGENICITY OF ORGANISMS IN DUST.

The early reports show definitely that it is not so common as was formerly supposed that tuberculous infection of the lungs is disseminable through dust. Whether the invasion by dust is through the respiratory tract or through the digestive tract, that is, by inhalation or by ingestion of food contaminated with dust, is a matter to be decided. Invasion probably occurs through both channels after the tubercle bacillus has entered the body, but the fact that dust may contain the tubercle bacillus means that such dust may be a conveyor of infection, and all that is necessary to establish a relation of disease and dust is to prove that the dust is laden with pathogenic germs. A number of studies showing the prevalence of pathogenic organisms among the colonies obtained by cultural methods manifests the fact that probably one out of 300 or 400 colonies is a pathogenic germ, and the degree to which the air may be laden is shown by Prudden's figures. It can readily be seen that a large number of individuals may be affected by one dust cloud, the dissemination of disease depending not so much upon the number of germs in a given amount of dust as upon the number of individuals coming into contact with large masses of germ-laden dust as suggested by Prudden. There is no longer doubt that the various forms of streptococci found in the dust are pathogenic, and the prevalence of bronchial and

nasal disease is more frequently due to a streptococcus infection than to any other.

There are very few investigations which show the absolute production of disease from dust, but one notable instance is that of the production of epidemic poliomyelitis (infantile paralysis) in monkeys by the injection of dust-sweepings from a room in which a patient had died several days previously. It is not necessary to prove the absolute relation of any kind of dust to any one individual case of disease. The statement of Prudden that dust in the streets is found to contain pathogenic germs in numbers at all measurable, since the dust occurs in such large amounts, is evidence enough. If it can be proved that certain diseases, particularly infections under the eyelids (conjunctival) and the upper and lower respiratory passages are due to certain types of bacteria; if it can be proved that these types occur in germ-laden dust, it is proven that the germ-laden dust does fill a definite relation to the dissemination of diseases. Certain of these diseases, such as external eye infections, bear a definite relation to incapacitation for service, and on that ground alone it is desirable, as a matter of economy, that dust in the streets be eradicated as soon as possible.

In relation to illness and death, since it is well established that germ-free and germ-laden dust bear a definite relation to infections of the upper and lower respiratory tract, the former secondarily and the latter primarily, it follows that the relation of dirt and dust to both can be roughly estimated to conform to the death rate from certain bronchial and pulmonary diseases, which occur so frequently as the result of dust dissemination.

Whether the dust dissemination is so important a factor in the spread of disease as the exposure of individuals in confined spaces to the "spraying" from coughing of other infected individuals, is open to discussion. The weight of evidence from more recent reports suggests that the latter method of infection is commoner. This does not, however, mean that dissemination of germ-laden dust is unimportant as a factor in endangering public health.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

GUNSHOT INJURIES OF THE NERVOUS SYSTEM—INTRADURAL, PERIPHERAL, CENTRAL—TREATMENT.

LONDON, Nov. 26, 1915.

GUNSHOT wounds have a special claim to attention at a time of war and they have been before the Medical Society of London during the last two months. Captain Trotter of University College, as mentioned in a previous letter, dealt with such wounds in nerves—not expecting to arrive at definite conclusions but rather proposing to show how we should try to apply our present knowledge to the material we have to deal with. He pointed out that interruption of a nerve cannot be compensated and restoration of its continuity does not insure its recovery, although it is a necessary preliminary. Bones, tendons, and in many cases blood-vessels when restored will resume function; these tissues are indigenous to the part, made on the spot, so to say; Nerve, on the contrary, is an alien tissue which at first invaded the part and must repeat the invasion under less favorable circumstances. An incomplete lesion or imperfect recovery may either of them be more disabling than a total loss of function. A divided nerve may be inert and the patient scarcely perceive his loss of sensibility; a partially divided or imperfectly recovered nerve may give rise to pain and extreme sensitiveness. These peculiarities interfere with the surgeon's work and may even expose him to the risk of increasing his patient's sufferings. Captain Trotter put forward as a basis for discussion the material with which he had had to deal (1) intradural nerve injuries—almost entirely lesions of the cauda equina, (2) peripheral nerve injuries. The latter are (*a*) typical and complete trunk lesions; (*b*) mixed lesions with division, complete or incomplete, of other adjacent trunks—chiefly observed in brachial and next to that in sacral plexus; (*c*) incomplete lesions without pain, usually due to combined bruising, laceration, scarring, and pressure; (*d*) incomplete lesions with pain; (*e*) pure pressure lesions, as from a prominence of bone or a foreign body. After some clinical remarks on these several types the question arises of what can be effected by surgery. Two alternatives are open, 1, implanting both ends into an adjacent trunk; 2, filling the gap with portions of a large cutaneous nerve, *e.g.* the internal saphenous. If the lesion is incomplete and resection thought unnecessary the nerve should be forced from other tissue and carefully wrapped in subcutaneous fat so as to secure exact coaptation, insulation, perfect asepsis, and muscular relaxation both before and after the operation.

Sir. F. Eve and Dr. R. S. Woods reported twenty-eight cases operated on for injuries of the peri-

pheral nerves—most of them in the war hospitals. It was always possible to get the two ends together by freeing the nerve above and below and flexing the nearest joint or adducting the upper arm. If a nerve seemed to be "hidebound," chiefly from thickening of the perineurium, they incised the thickened tissue. In one case the bullet smashed the center of the clavicle; so the bone was divided and fragments found pressing on the anterior divisions of the fifth, sixth, and seventh nerves. Dense scar tissue enveloped them and was removed and the clavicle wired. The axillary artery and vein, usually involved in the scar tissue, had to be ligatured in one case, above and below the lesion. All the cords of the brachial plexus were matted together and adherent to the subscapularis muscle. The point to determine in these lesions is whether to separate the injured nerve from surrounding tissues, or resect it. In doubt, the amount of drainage may sometimes be shown by blunt dissection of the nerve bundles from above into the cicatrix to see if they are continuous across it. The disappointing feature in the treatment of these nerve injuries is the long period required to complete the repair and restoration of function in the most favorable circumstances.

Dr. E. F. Buzzard followed, saying three points required consideration: (1) Cases which should be operated on; (2) what should be done; (3) relief of pain. As to the first, in case of doubt it was wise to explore, whether local conditions were favorable to return of function. A peripheral lesion of nerve should be carefully examined with both finger and eye. Partially divided nerves would recover incompletely, whether excised or only sutured. But severe pain and hyperesthasia might continue for months, even rendering excision needful. Injection of nerve end with alcohol would relieve pain.

Mr. Jocelyn Swan had had 63 cases; 38 operated on, 41 explored, 6 declined operation, in 3 it was not thought advisable, 4 had been deferred, in 12 recovery of function took place in two to four weeks after the injury. These last had been called "nerve concussion," and it was not easy to say whether actual damage had been done to the nerve; a strong faradic current produced a reaction. No operation should be done until the surface wound had firmly healed. We could not distinguish between complete division and binding by scar tissue. In the latter case excision of both scar and tissue had been successful.

Another discussion on gunshot wounds was held on the 15th inst. This was devoted to head wounds of this kind and opened by Mr. Sargent, who said operation was not so urgent for these cases as for abdominal wounds. They did not seem to suffer much from a journey before being subjected to operation, but they were not in a fit state to be transported immediately afterward. Early, thorough cleansing was not in the same category as removal of foreign bodies without the aid of *x*-ray examination. The cerebral disturbance greatly varied, and there was no relationship between the cranial and cerebral injury. Nothing would influence the brain symptoms unless the dura were injured, but if this was so lacerated as to open an avenue for infection, whatever was done to the wound might, by diminishing the risk of infection, prevent or minimize further destruction. Exploratory operations for possible hemorrhage had no place in the treatment, for such wounds are almost always septic and opening the dura endangered meningeal infection. Operations had been undertaken to minimize the danger of intracranial suppuration—the chief cause of death or disablement. Many patients arrived at field ambulance or clearing station with great defect of scalp, bone, and dura with protrusion of brain, blood, and cerebrospinal fluid issuing, mostly unconscious or noisy. Such were fatal in a few hours, though in some less brain substance was lost than was at first supposed, and recovery eventually took place. No search for fragments should be made. In minor cases in which there was fracture but no laceration of dura, traumatic epilepsy might result from the damage at the time of injury, so that operation for such was of no avail, and in depressed fractures only when they were extensive and broken bone is a septic wound threatened to necrose. Bullets and fragments of shell were best left alone unless their position made removal quite easy or they caused distinct symptoms. When the dura was not lacerated it was very dangerous to incise it; when it was and intracranial pressure increased dangerously, lumbar puncture or contralateral decomposition was safer. Dr. Gordon Holmes had worked with Mr. Holmes and one of their chief aims had been to insure safe transfer to England for more deliberate treatment. Major Rowling urged more ultimate cooperation between surgeons at foreign camps and at home, and a probe should be used to explore a wound—the finger was objectionable. The seriousness of the injury could not be known without exploration. Fractures of external table were usually accompanied by the same of the internal and should be operated on earlier than it often is, before sending to England. Mr. Walter Trotter dwelt on the way serious symptoms sometimes remain latent, and advised operation as soon as such supervened. Captain Sidney Smith had had 400 cases in a special ward for head injuries. Only 96 were trephined; the mortality was high, as the worst cases were sent to the ward to avoid a further journey. Professor Wilson and Sir V. Horsley sent a written communication saying the point was to prevent the spread of microbic invasion of the brain from the surface and tract of the wound, our means of doing which depended on (*a*) the species of the microbe found; (*b*) the nature of the lesion it may produce. From their observations and experiments they consider that in all cases a bacteriological diagnosis should be made, that all these injuries should be disinfected from the earliest moment possible, by excision of the wound or no closure of it, and repeated dressings and the appropriate antiseptic lotions. In streptococcal infections the free use of antistreptococcal serum is especially absolutely essential. Mr. W. Pearson had had experience of these head cases both in France and England, the result being a great modification of his previous views, according to the type of case and the time that had passed.

Pituitary Secretion.—Cow from his researches is of the opinion that the products of activity of the pituitary body are secreted into the cerebrospinal fluid, whence their gradual diffusion into the blood stream may follow—*Journal of Physiology.*

Iodine in Erysipelas.—Magi records the brilliant results following the painting of the affected area with tincture of iodine. In the severest cases an antistreptococcus serum is used as a supplementary measure.—*Il Policlinico.*

1. Address. The Danger of Ether as an Anesthetic. W. W. Keen.
2. Pregnancy and Diabetes Mellitus. Elliott P. Joslin.
3. Surgical Specialties in Hospitals. Paul Thorndike.
4. Observations on the Etiology and Treatment of Heart Disease. Paul Dudley White.

1. The Dangers of Ether as an Anesthetic.—W. W. Keen delivered this address at the Massachusetts General Hospital on the sixty-ninth anniversary of Ether Day, October 16, 1915. A questionnaire as to immediate and delayed ether deaths, sent to the members of the American Surgical Association, resulted in the receipt of 67 replies, in 20 of which the figures were exact. These 20 returns showed that among 262,002 etherizations there had been 34 deaths, or one death in 7,706 cases. The 47 other returns in which the estimates were only approximate gave the number of etherizations as 356,500 and the estimated number of deaths 73, or one death in 4,884 cases. Both the estimate and the exact numbers show that we have three times as many deaths from ether as occur in Great Britain. This calls loudly for reform. Among the dangers of ether discussed are its inflammability, the danger to the patient of an "inundation of mucus," respiratory dangers, post-operative pneumonia, anuria, glycosuria, and acidosis. In concluding Dr. Keen says: "In my opinion 'straight ether' by the open drop method on an Allis inhaler or a simple mask is by far the best and safest routine anesthetic." Since it is evident that we should obtain better results we need: 1. Many professional anesthetists. 2. The use of an anesthesia chart in all cases. 3. The collection of statistics, best by the American Surgical Association at intervals of five years. 4. Instruction of all medical students in the theory and practice of anesthesia. 5. Straight ether by the open drop method as a routine method instead of mixtures and sequences. I believe all of the latter to be more dangerous than ether. 6. More accurate dosage of the ether by the anesthetometer as a gas on the basis of its anesthetic tension, *i.e.* the partial pressure of the ether vapor in the respired air. Every case of anesthesia requires unremitting watchfulness from first to last.

2. Pregnancy and Diabetes Mellitus.—Elliott P. Joslin reports seven cases of moderate or severe diabetes and seven cases of mild diabetes in pregnant patients, and from a study of these cases concludes that the secret of success in the treatment of pregnant women with sugar in the urine is: 1. To have the patients under constant supervision throughout the course of the pregnancy and for some months after confinement. The cause of the death of Case No. 604 may well be attributed to the neglect of this precaution. 2. Treatment should follow exactly the same methods which are employed in the treatment of the usual case of diabetes. 3. Even when sugar appears to a slight extent in pregnant women, it should be carefully watched and controlled by diet. 4. The advantages of a cesarean section should be borne in mind. 5. Whereas ether anesthesia may work well, it is probably not so safe as gas and oxygen. If ether should be used, as brief an anesthesia and as little ether as possible should be employed. 6. Finally, many statements occurring in the literature of pregnancy and diabetes must be revised. Pregnancy in diabetes does not demand immediate abortion, even if acidosis is present. It cannot yet be accepted as proven that pregnancy aggravates diabetes. Nursing is not contraindicated following confinement, for the diversion it affords the patient may offset the extra demands thrown on the metabolism.

3. Surgical Specialties in Hospitals—Paul Thorndike considers the functions of the hospital in three fields, the efficient cure of the sick; the proper use of its material for advancing the cause of science; and the teaching of doctors, students, and nurses. Theoretically it would seem at once for the best interest of patient, hospital, and medical school that special services shall exist. But the question arises as to where this theory is leading us. How far are we to go with it? Is the general surgeon to disappear? Are we to have specialists in all branches of surgery? Are hospital house officers and nurses to be brought up as specialists from the start? Are the members of visiting staffs to be confined to a small field of work, or at all events to a smaller field than meets their inclinations and desires? Are the orthopedic men, the aurists, and the urologists to be followed by many other special men? Obviously not, though it may seem so at the present moment. The problem is one which will gradually develop and settle itself without much guiding from the profession. It would seem that the general surgical service must exist for many years to come and that various special departments in surgery must be a problem for the individual hospital. The writer describes a plan by which a genitourinary service was developed at the Boston City Hospital without depriving the other surgical services of their genitourinary cases.

4. Observations on the Etiology and Treatment of Heart Disease.—Paul Dudley White presents a study of the relationship of the more important abnormalities of the heart beat to etiology and treatment as seen at the Massachusetts General Hospital during the year August 1, 1914, to August 1, 1915. During this time 100 cases of auricular fibrillation were found in the wards and outpatient department of the hospital. From his observations on these patients the writer summarizes as follows: 1. The male sex has been found to be more subject to auricular fibrillation, auricular flutter, heart block, and alternation of the pulse than has the female sex. 2. The older the patient with heart disease the more subject he has been found to be to serious abnormalities of the heart beat. 3. Auricular fibrillation and alternation of the pulse occurred at the same ages, most frequently in the fifth and sixth decades. 4. Rheumatic hearts usually showed normal mechanism or auricular fibrillation, much less commonly *pulsus alternans*. 5. A considerable percentage (36 per cent.) of syphilitic hearts showed alternation of the pulse; few were fibrillating. 6. A patient with cardiac insufficiency in the course of cardiorenal disease was very apt to show *pulsus alternans*, either constant or more frequently only after ventricular premature beats. 7. Cardiosclerosis often resulted in the production of fibrillation and alternation. 8. Hyperthyroidism of long standing was sometimes attended by auricular fibrillation. 9. Alcohol, tobacco, tea, and coffee appeared to play no direct part in the production of serious disorders of the heart beat. 10. Two-thirds of the patients with auricular fibrillation, one-half of those with alternation of the pulse, and one-third of those with normal mechanism in the present series showed physical signs of cardiac insufficiency. 11. Digitalis was used in 88 per cent. of these decompensated cases, almost always in the form of pills of standardized leaves. Intravenous medication was used in urgent cases only. 12. Morphine was given beneficially in nearly one-half of the patients with physical signs of insufficiency, often one dose sufficing to give the patient the first comfortable night in weeks. 13. Venesection was found useful in a few urgent cases. 14. The change in diet to five small meals daily was often much appreciated by the patient.

6. Syphilis of the Cardiovascular and Renal Systems. Joseph Barach.
7. Persistent Gonococcus Infection. M. Zigler.
8. Gastroenterostomy. John B. Haeberlin.

1. **Arteriosclerosis as a Cellular Disease.**—Louis Faugeres Bishop states that the disease called arteriosclerosis, which is really cardiovascular renal disease, is primarily due to a disturbance of metabolism extending over a long period of time. This disturbance of metabolism consists in sensitization of the cells of the body to particular proteins ordinarily found in food. Meat proteins are most often to blame. Fish and egg proteins are sometimes to blame. This process is subsymptomal for five, ten, or fifteen years, until such a time as a sufficient number of cells have been destroyed to impair the functions of the organs. This gives rise to symptoms and the disease is discovered. The remedy for the disease is to be found in the discovery and removal from the diet of the offending proteins, and in the correction of metabolism by physical methods, particularly exercise; attention should also be directed to the intestinal tract. We cannot throw overboard all that has been said of late years as to autointoxication, intestinal stasis, and so on, but there is a remedy which is the best for dealing with the intestinal condition and that is serial doses of castor oil. In addition to this we have to treat the individual. The psychical side of these persons is very important; they need assurance.

4. **The Puerperium.**—J. O. Arnold makes a plea for the individualization of the puerperal woman and for a more rational conduct of the puerperium. He discusses seven points with reference to which mistakes are commonly made. 1. He believes it a mistake to suppose that the process of involution is favored by boxing up the uterus in abdominal pads and a tight binder. 2. It is a mistake to attempt to keep every puerperal woman flat on her back for a great length of time. 3. There is seldom any reason for starving the puerperal woman for three or four days. On the contrary, judicious liberality in food gives better lactation and an earlier and more satisfactory convalescence. 4. It is usually, if not always, a mistake to suppose that an elevation of one or more degrees of temperature without other apparent cause is of gastrointestinal origin. 5. A rather frequent mistake is that of thinking a postpartum high temperature which does not readily clear up with a purgative, or that is accompanied by a foul discharge and some tenderness and subinvolution, is an indication for intrauterine douches, curettage, or other questionable interference. Instead, facilitate drainage by elevating the head of the bed and give one or more doses of pituitary extract or of ergot. 6. Another traditional custom for which no reason exists is the old idea that some more or less complicated specific treatment must be employed to dry up the milk if such a step should be necessary, whereas all the treatments generally employed are useless, and the one simple and invariably successful method is to let the breasts absolutely and severely alone. 7. Finally, with reference as to when the patient may leave her bed, it is a mistake to fix upon any day, early or late, as a routine time for getting puerperal patients up. They are certainly not all alike and should not be made to conform to a common rule.

7. **Persistent Gonorrhea.**—M. Zigler reports a case of persistent gonococcus infection which lasted eleven years in spite of almost continuous treatment and which emphasizes the facts that there are certain cases of gonorrhea in which the gonococcus lives for years in the genitourinary tract; that ordinary smears for gonococci, after the infection is chronic are practically worthless; that cultures should be taken in every case before it is discharged, and that in order to obtain a satisfactory specimen of the fluid for cultural examination for the gonococcus, one should be familiar with the technique of prostatic massage and stripping of the seminal vesicles. Attention is called to the fact that, while a good many patients have vague subjective and objective symptoms after gonorrhea, in the large majority the disease is not contagious, the case reported being simply one of the exceptions.

8. **Gastroenterostomy.**—John B. Haeberlin gives a survey of the three operations which compete with one another in gastric surgery, namely, gastroenterostomy, Finney's operation or gastroduodenostomy, and Rodman's operation or resection of the ulcer bearing area, and concludes that in all cases in which there is suspicion of cancer reseetion should be done, the condition of the patient permitting. However, in other cases the excess percentage of mortality of the resection operation over gastroenterostomy, is so much greater than the percentage which develop into cancer after gastroenterostomy, that there are but few who would take this added risk. The mortality from gastric resection is 20 per cent. greater than the mortality of gastroenterostomy. The proportion of cancer developing from ulcer following operations for gastroenterostomy is probably as low as 1 per cent. Modern posterior gastroenterostomy, performed in accordance with proper indications, considered from all angles with competing operations, as to ease of performance, complications, early and late, low mortality, and its after results, remains the operation of choice of the vast majority of surgeons.

1. **Magic and Medicine.**—Francis Carter Wood delivered this address at the opening of the College of Physicians and Surgeons, Columbia University, New York, September 19, 1915, in which he showed that human nature, even in this scientific age, searches for something to satisfy its desire for magic, a something which the scientific physician no longer supplies. The popular mind has found in radium such that appeals to its love of the mysterious. The newspapers herald the wonderful cures which radium produces but we

know to-day that it will certainly cure only a very small number of cancers and will do nothing which cannot be done by surgery. The result of the furore and publicity on this subject is that it is not always possible to get patients to submit to surgery for the removal of a tumor; they are so anxious to be treated with radium. Analyzing this love for the mysterious the lecturer finds in it a part and parcel of that yearning for a power and perfection beyond the mere limitations of the flesh which has led men on for all time, but which is capable of diversion to evil ends when exploited by the unscrupulous. The remedy against the wiles of the quack and the sensationalism of the press is education. With a deepening of real knowledge comes intellectual charity while a diminution in the sensationalism of the press and a corresponding increase in the charity and honesty of such medical information as is suitable for the public, the really excellent educational campaigns now being conducted by physicians through the publications of medical societies and reports of public health officers and of certain publicists who have raised their voices against the widespread sale of quack medicines, all of these will abate somewhat the density of popular ignorance. It is our duty as physicians to lead this intellectual reform by refusing to be limited by a narrow professionalism, both in education and in practice and to regain that position of intellectual leadership which some of our great predecessors held in virtue of the fact that they were first of all great men, and only secondly, accomplished practitioners.

2. **Hospital Efficiency.**—Arthur A. Howard gives the results of the follow-up system in connection with the Boston Dispensary Hospital for Children. The data seem to indicate that home environment has a definite bearing on the progress made by the patients after leaving the hospital, and that the control of the patients through the follow-up system and the social service department was a factor in producing this progress. To be of real value this system must apply to all cases, not to occasional or selected cases; it must be a continuous part of the hospital routine; and it must not be merely a negative factor, finding out the patient's condition at periodical intervals, but a positive factor, exercising control over conditions. The cost of follow-up work should be turned into actual saving to the hospital by decreasing the number of readmissions.

3. **Epiphysis Transplantations.**—S. L. Haas describes the method used in making these transplantations, the ten sets of experiments which were made and concludes as follows: 1. From the practically uniform failure of increase in length of the bones after transplantation of the epiphyseal cartilage, either alone or with an accompanying piece of the epiphysis and diaphysis, both in reimplantation and autotransplantation, it must be concluded that epiphyseal cartilage loses its power to functionate after such transplantations. 2. As the degenerative processes were more advanced in autotransplantation than in reimplantation, it can be almost certainly predicted that there would be a more marked degeneration in homotransplantation. 3. Whether a small or large sized transplant was taken was of no consequence, as there was the same failure of growth in every instance. Incisions into the periosteum or boring holes into the cortex hastened the degenerative processes. 4. There was marked disturbance of growth following the two-stage autotransplantation, in spite of the fact that osseous union was secured before severing the epiphyseal transplant from its surrounding and nourishing tissues. 5. The epiphyseal cartilage must be considered as a very vulnerable tissue, its viability being directly dependent upon its blood supply.

5. **Nitrous Oxide at Lakeside.**—A. R. Warner describes their experience with nitrous oxide gas used for anesthesia during the past eight years, and the method which he has devised for its manufacture in a sufficiently pure state to be without poisonous effects. The advantages of this anesthetic when the gases are used are that it is not disagreeable or irritating, consciousness is lost promptly, vomiting is extremely rare, pneumonia and post-operative shock are much less frequent and the patients are able to leave the ward sooner than with other anesthetics. The lesser degree of muscular relaxation with nitrous oxide anesthesia which is sometimes annoying to the surgeon may be overcome by mixing a little ether vapor when the relaxation is needed.

7. **Wassermann Test.**—Josiah J. Moore gives the results of the routine use of the Wassermann reaction as a routine measure on practically every person attending the medical dispensary clinics of the University of Illinois College of Medicine. Genitourinary, gynecological, pediatric, nervous, dermatological and surgical cases were not included. Fifty-six positive Wassermann reactions were obtained in the routine examination of 418 patients. Only 50 per cent. of those with a positive test gave a history of having syphilis. Twelve weakly positive reactions were obtained, four patients being tested only once; without history or symptoms the diagnosis of syphilis could not be made in these. Repeated negative tests were of assistance in diagnosing non-syphilitic conditions in which false histories of previous infections were obtained. The positive Wassermann test is of inestimable value in the diagnosis of syphilis in the medical dispensary. The unreliability of histories and the protean nature of the disease make it extremely difficult of diagnosis in all cases.

8. **Venereal Disease Clinics.**—Michael M. Davis states that the problem of venereal disease is in some ways a parallel public problem to that of tuberculosis, but it has received much less attention. If we recognize the enormous amount of syphilis and gonorrhea in the community, if we believe it to be a fact that the mass of these cases do not now receive adequate treatment, that most patients cannot afford adequate treatment, then we must turn to organized medical service in clinics as a resource to provide this treatment. The establishment of out-patient clinics on a large scale, administered as public health measures, for the diagnosis and treatment of syphilis and gonorrhea, is a practicable, necessary, and immediately desirable step in the campaign against these diseases.

10. **Syphilis of the Spine.**—James L. Whitney and Walter I. Baldwin state that for some years in the University Hospital they have recognized as extremely common and very characteristic, certain lesions of the spine found in syphilitics. To put these strong impressions in the form of figures a study of 100 cases of syphilis was undertaken, with special reference to conditions of the spine. The results were rather more striking than was anticipated. Out of the 100 cases there were only twenty-six with normal spines, while six more were classified as doubtful. The remaining sixty-eight cases had spinal abnormalities of some kind and of these all but four were of a type which the authors have learned to consider more or less characteristic of syphilis. This is a localized stiffness of the spine in conjunction with hypertonicity of the uninvolved spine and the pelvic and hip joints which is almost pathognomonic of syphilis. It is found in obsolete as well as in active cases. It is a sign easy to

demonstrate. A negative Wassermann reaction should not be interpreted as excluding syphilis in the presence of other signs which suggest joint syphilis.

11. **Subperiosteal Resection.**—D. B. Phemister states that there is no uniformity of results after subperiosteal resection either in healthy bones of animals or in diseased and healthy bones in man. The full explanation of this has not yet been determined, but there are a number of known factors of importance, such as the presence or absence of infection and the technique of freeing from the bone the periosteum or involucrum which is left behind. In view of the clinical and experimental data now at hand, showing the frequent failure of regeneration, subperiosteal resection should be reserved for selected cases of osteomyelitis in which there is extensive necrosis of the bone, and especially when it is located in areas inaccessible to operation, as the posterior part of the tibia. Its use should be limited to parts of the body in which there is some other bony support, and should almost never be used where there is only one bone in the extremity, as later sequestrectomy gives better results in such cases. The operation should not be performed too early while the infection is severe, and before a soft involucrum has formed, nor too late after the involucrum is so ossified that an insufficient amount of osteogenetic tissue is removed. In case of failure of regeneration, the defect can best be repaired by free transplantation of bone, although a missing shaft of the tibia can be remedied by division of the fibula above and below and shifting it to the tibial defect, a method first used by Huntington.

7. 1,000 Doses of Phenolphthalein. J. C. McWalter.

1. **Bright's Disease.**—Samuel West delivered this lecture before the Hunterian Society on October 13, 1915. In it he adheres strictly to Bright's original classification, acute Bright's disease and chronic Bright's disease, and maintains that there is no established relation between these two forms. In discussing acute Bright's disease several cases are cited in which granular kidney could be excluded and which could not be explained by acute nephritis since they were ushered in by uremia which is not an early, least of all the first sign in acute nephritis, and in which the symptoms quickly subsided and the patients regained apparently normal health. The condition was obviously renal in origin, but it was not one that is met with in any of the recognized forms of kidney disease. The author is inclined to wonder whether this was the type of case designated by the old-fashioned expression "acute congestion of the kidney" which had been dropped out of our nomenclature. In the consideration of chronic Bright's disease the point is dwelt upon that such a classification as contracted white kidney and contracted red kidney is very indefinite and unsatisfactory, and a protest is made against the theory implied that the difference in color designates a difference in origin. In speaking of the relation of arterial thickening, the raised blood pressure, and the kidney lesion in granular kidney the author expresses the belief that so far as granular kidney is concerned, the primary change is renal, that the raised arterial tension is the result of the renal lesion, and the arterial changes are the consequence of that, the heart changes being secondary and consequent on the arterial. The cause of the primary renal disease is still unknown. The one fact that seems abundantly clear is that these problems can only be solved by clinical observation. After discussing the retinal arterial and venous changes and albuminuric retinitis says that the generally accepted statement that albuminuric retinitis is a late symptom in granular kidney is true of the exudative form, but that the degenerative form has a much longer duration of life, he, himself, having known of cases of seven years' duration and longer. If eyes were examined earlier in a routine way in every case in which granular kidney was suspected, the white spots would be detected much earlier, and the subsequent duration of life therefore would be much longer than is usually stated.

2. **The Cerebrospinal Fever Problem.**—H. Warren Crowe confines himself to such aspects of this disease, its treatment, and economic control as came within his experience during the recent epidemic among the troops, refers more particularly to new methods of technique which proved of great value in saving labor and time, and describes certain researches which may lead to a more rapid method of identifying the meningococcus in the future. The practical results were as follows: In diagnosis the examination of the spinal fluid seems most satisfactory. This was done by enriching the spinal fluid by 1 per cent. glucose, incubating 24 hours, and then examining. In the treatment, serum was used which had been tested and found to agglutinate the organism isolated, and was followed by small doses of an autogenous vaccine. In the diagnosis of carriers a medium should be used containing hemoglobin or a near derivative. The ultimate recognition of the organism is to be gained by a simple agglutination test. In the treatment of carriers the mildest method, for example, permanganate of potash 1 in 10,000 was more successful than antiseptic mixtures. The writer adds a note on a method of isolating streptococci and other delicate organisms from wounds, in face of gross contamination.

3. **So-Called Trench Fever.**—G. H. Hunt and A. C. Rankin give a description of a condition based on the observation of 30 patients, though other cases have been noticed in which the symptoms were identical, but in which the fever ran a different course. Various bacteriological examinations have been made with the object of finding a specific organism but thus far none has been discovered. After the patient has been under observation for a few days the diagnosis is readily made. It is more difficult when the patient is first admitted to the hospital, at which time it rests on the following features: 1. A history of headache and pain in the legs and back, without catarrh or gastrointestinal symptoms. 2. Slight constitutional disturbance even with high fever. 3. A fairly clean tongue. 4. Absence of rash, splenic enlargement, and bronchitis. It seems that this "fever" was not contagious in any high degree. Quinine in five to ten grain doses and salicylates in 30 grain doses given three times a day did not appear to influence the temperature to any appreciable extent.

4. **Bacterial Antagonism.**—Leonard Colebrook states that in the course of his investigation of meningococcus carriers he has noticed on several occasions that when the meningococcus began to disappear from the nasopharynx it was at once replaced by great numbers of pneumococci or streptococci. Moreover on at least two occasions the disappearance of the meningococcus seemed to be determined by the onset of an aute cold in the head. The question arose had these pneumococci

and streptococci simply entered on the field vacated by the meningococci or had they also played an active rôle in supplanting the invader? The experiments described were made with the view of showing if there was any antagonism between these organisms on artificial media. The experiments on meningococcus carriers show that the pneumococci were apparently unable to establish themselves in the nasopharynx of these carriers, for although implanted in very large numbers they could not be recovered in any quantity from swabs taken after a few hours or on the following day. In one case the pneumococci probably gained a slight foothold at first for the meningococci almost disappeared from the swabs for nearly two days, but after that time regained their early predominance. This partial success suggests to the author the possibility that with more knowledge of the conditions which enable the inhibitory organism to establish themselves, the method might prove of some value.

6. Blackwater Fever.—R. W. Burkitt of the East African Medical Staff presents a report on a method by which he has been successful in treating some serious cases of blackwater fever by the administration of potassium and sodium bicarbonate and chloride of calcium. He regards these remedies as blood alkalinizers and his view appears to be that the symptoms in blackwater fever are in all probability due to a lessened alkalinity of the blood, this being a by-product of the condition preceding hemoglobinuria, and that this by-product when it reaches a certain point causes a breaking down of the blood elements.

7. 1,000 Doses of Phenolphthalein.—J. C. McWalter states that he has prescribed something more than 1,000 doses of this drug and finds it particularly useful in cases of intestinal toxemia. It offers ideal advantages because what is required is a mild antiseptic, capable of being taken for a considerable period without toxic or cumulative effects, and yet free from those irritating effects of the mucous membrane of the intestine which renders most purgatives harmful in these cases. In mucomembranous colitis phenolphthalein will be found in doses of half a grain daily eminently satisfactory in preventing enterospasm, easing pain, checking the excessive secretion of mucus, improving the neurasthenia, and generally improving the patient's condition.

4. Auscultation of the Heart of the Recruit. James Kingston Fowler.
5. Tartar Emetic in Kala-azar. Percival Mackie.
6. Bilharziosis in Natal. F. G. Cawston.

1. Clinical Aspects of Typhus Fever.—P. C. T. Davy and A. J. Brown describe the conditions at the German prison camp at Gardelegen, where the total number of prisoners is from 11,000 to 12,000 men, and where during their stay they observed some 2,000 cases of typhus fever. The evidence seems to point to the body louse as the carrier of the disease. There is no evidence that the infective agent was carried by any of the dejecta. Their description of the symptoms and onset of the disease agrees with that of others. They call particular attention to epistaxis at some time in the course of the disease as extremely characteristic. During the epidemic they were accustomed to regard it as pathognomonic. In speaking of the treatment the authors state that the secret of successful treatment of typhus lies as with enteric fever in the nursing of the patient. Force of circumstances condemned their patients to starvation diet, and they did well on it. Absolute rest in the recumbent position is essential from the onset. Plenty of liquid should be given throughout the disease. Solid diet of the most easily assimilated character should be given as soon as the tongue begins to clear. The patient should be kept in bed until the pulse has been normal for at least a week. In those cases in which special attention could be paid to the mouth, the ear, and the parotid, complications did not occur. Generally speaking two lines of treatment were attempted: 1. Early and continuous stimulation, mainly by hypodermic and intramuscular injection of camphorated oil, and to a lesser extent of strychnine and ether. The immense crop of abscesses which resulted from the use of the camphorated oil condemned it and especially so in the absence of any perceptible beneficial result. 2. Purely expectant and symptomatic treatment combined with the free use of morphine in every case in which it was not obviously contraindicated. The writers regard morphine as a sheet anchor in most cases and state that they have never had cause to regret its use.

2. Recrudescence of Local Sepsis in Wounds.—R. H. Jocelyn Swan and Kenneth Goadby, in an attempt to gain information on the questions raised involving the power of organisms to remain dormant in the tissues, and to become suddenly active after some slight surgical interference, have in a long series of cases made routine bacteriological examination of the tissues surrounding fragments of shell, shrapnel bullets, etc., which have remained buried in the body for varying times, but in which the wound of entrance has healed. They have found that organisms may lie dormant without causing any clinical symptoms, and this explains the lighting up of local inflammation long after the external wound is healed. They have also found a type of case which owes its peculiar features to a process analogous to anaphylaxis; the tissues, having originally been subjected to constant doses of bacterial poison, are, after an interval, subjected to an anaphylactic dose of the original poison.

4. Auscultation of the Heart of the Recruit.—James Kingston Fowler says that the memoranda issued by the War Office on the significance of abnormal signs in the heart of the recruit suggest that it may be well to call attention to the following precautions which should be observed in the examination of all cases presenting murmurs. 1. The exact period in the cardiac cycle occupied by the murmur. False murmurs are often not exactly synchronous with the commencement of systole or diastole; they may precede or follow the one or the other. 2. The site of maximum intensity and the line of conduction of the murmur. These do not usually coincide with what is found with similar murmurs of organic origin. 3. The condition of the lungs. With doubtful apex murmurs evidence of pulmonary engorgement is strongly in favor of organic valve disease, as that condition is almost invariably absent in the reflux of anemia. 4. The effect of change of position upon the sound. *It is essential to examine every case of suspected valve disease both in the standing and recumbent position.* It may be stated with confidence that an opinion given in a doubtful case without observing this precaution is of no value. Functional and false murmurs often disappear when the patient lies down, while an organic murmur, especially that of mitral stenosis, may be only audible in that position. A murmur which suddenly and completely disappears when the patient lies down, provided there is not at the same time any marked alteration in the pulse-rate, is

almost certainly not due to organic disease of a valve. 5. It is important in all cases to auscultate the trachea. A murmur audible in the trachea may be due (1) to the conduction of the murmur of aortic stenosis; or (2) to the impulse of an aneurysm; or (3) to the impulse of the heart causing an air wave in the bronchi and trachea, this latter being by far the most common cause of tracheal murmurs. Mitral murmurs are not audible in the trachea. 6. False murmurs often disappear completely when the breath is held. 7. The state of the pulse may at once negative a suspicion of organic disease founded on the presence of a murmur.

5. Tartar Emetic in Kala-azar.—Percival Mackie reports two cases of leishmanial infection successfully treated by antimony. The first case is interesting in that the disease began in a fissure of the lip and apart from any exposure to insect infection; because of the presence of a subcutaneous nodule due to Leishmania which had no discernible connection with the outside surface, and because of the good effect of the antimony in rapidly sterilizing the cutaneous lesion and its slower action on the mucous ulceration.

Berliner klinische Wochenschrift.

October 25, 1915.

War Experiences with Infectious Diseases.—Grundmann continues his article with a very thorough account of his thirteen cases of cerebrospinal meningitis. There was but slight evidence of transmissibility and the cases occurred in April and May, the months of preference. The disease began suddenly with headache and fever, relatively slow pulse, vomiting, vertigo, stiff neck, herpes labialis, Kernig's sign, increased reflexes, meningococci in the lumbal punctate. Headache yielded only to morphine or lumbal puncture. The history of a severe, fatally ending case is as follows: Patient admitted with severe headache after a record of perfect health. He had been seized in the night with a chill, fever, headache, vertigo and delirium. Next day he was quite unconscious, and over the trunk and extremities was a marked bluish red small macular exanthem. There was suspicion of typhus. Upon contact the patient screamed and trembled, and there was some fibrillary twitching and rigidity of the limbs suggesting tetanus. Examination of lumbal punctate revealed the presence of meningococci agglutinated by patients' blood serum. No meningococci in nose and throat smears. Patient lived five days and autopsy confirmed diagnosis.

Mixed Infection—Dysentery and Typhoid.—Soldin states that proof in these cases is hard to furnish. A case given in detail is summed up as follows: the patient was suddenly stricken with acute, gastroenteric symptoms upon which followed quickly typhoid symptoms, as mental confusion and enlarged spleen. The stools had from the first suggested dysentery, containing shreds of mucus. Bacteriological examination revealed the presence of both the typhoid bacillus and that of pseudo dysentery. The temperature curve was lytic which of course did not exclude typhus. The mental confusion and enlarged spleen have never been seen by the author in dysentery. Persistent occurrence of blood in the stools after a certain period pointed to dysentery but did not exclude paratyphoid. Late hemorrhage from typhoid ulcers is of course a different type of symptom. The agglutination test was positive both for typhoid and paratyphoid. It is very rare, as already asserted, to see a strict coincidence of dysentery and typhoid, although we see either disease appear during convalescence from the other.

Treatment of Pneumonia by Chemotherapy.—Loeb treated twenty-four cases with a ethylhydrocuprein and a quininesalicylic acid ester. At the end of forty-eight hours most of the patients showed some form of improvement—either a fall of temperature, improvement in headache, clearing of the sensorium, etc. In one patient only was fever aborted outright. In all the others it rose again, once more to fall when the drugs were repeated. The temperature finally fell before the critical time. In all respects the drugs seemed to attack the underlying sepsis as shown by the action on the heart. While the ethylhydrocuprein caused no unpleasant by-effects the other drug caused mild cinchonism in several cases. There was no mortality in the author's series, nor any sequelæ.

Deutsche medizinische Wochenschrift.

October 28, 1915.

The Hunger Sensation.—Müller regards this sensation as having a multifold origin. It may in part depend upon the primary emptiness of the stomach but this the author disbelieves. His view is that a certain degree of absence in the blood of nutriment is responsible for that condition of the stomach accompanied by rumbling noises and sense of pressure. The latter he attributes to the muscle tonus of the empty organ. Emptiness in the colon may also cause spasms (sense of tenesmus), contractions of the stomach artificially produced give rise to the sense of emptiness and hunger. As it is difficult to differentiate between the two last mentioned so is it likewise to differentiate between hunger and appetite. The latter is associated with a particular kind of food. It is a proverb that "appetite comes with eating" while hunger should diminish with eating. After prolonged abstinence appetite becomes less selective. The author finds a close parallel between hunger and sexual sensations and connects both with the encephalon since the mind is able to stimulate or inhibit either.

Appearance of Immature Leucocytes in the Blood in Infectious Diseases.—Photakis sums up in saying that the entrance into the blood of young forms of leucocytes gives us an important datum for the severity of the irritation of the bone marrow as determined by the virulence of the infectious microorganism. This means to a certain degree the severity of the disease itself. Naturally, we cannot determine the entire status from the blood count alone, and other clinical evidences must be invoked.

Chronic Pancreatitis.—Einhorn of New York considers this condition from the standpoint of the internist. As a general proposition this affection agrees well with the old conception of lientery. Exact diagnosis is naturally very difficult. In one form the most conspicuous symptom is diarrhea. In another, the disease picture is chiefly diabetes, indigestion, and general weakness. Finally in a third group gastralgia, and attacks of constipation with periods of weakness stand forth as frequent symptoms. The author cites cases of each type. In one case a patient, hitherto sound unless damaged by alcohol, began to complain and for two years past has had abdominal pain, loss of weight and occasional diarrhea. A diagnosis of cancer of the stomach was finally made. Laparotomy discovered only a few gastric adhesions. The appendix was removed. For a time the patient gained but soon the old train of symptoms appeared, much aggravated, and in spite of treatment, the case went from bad to worse until death took place, from malnutrition. In this case the diagnosis must have lain between gastric cancer and chronic pancreatitis from the start, and the former had been rigidly excluded. No autopsy is mentioned. The diagnosis of chronic pancreatitis rests largely on the clinical picture of lientery.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Anniversary Meeting, Held November 18, 1915.

THE PRESIDENT, DR. WALTER B. JAMES, IN THE CHAIR.

Disease and Crime: An Analogy.—THE PRESIDENT said that the question proposed for discussion at this anniversary meeting, was: "Has not the time come when ethics, the law, and medicine should join hands to form a constructive program, aiming to do for crime what has been done for disease through systematic study and classification leading up to effective measures of prevention and intelligent individual treatment?"

The Concern of the Public in the Problem of Crime.—GEORGE W. WICKERSHAM, Esq., president of the Bar Association of New York, said that it seemed to him that the problem of crime should first be presented by considering a few statistics showing the extent of crime in our country and our State. The United States Census for 1910 showed that in that year 493,934 persons were committed to prisons, county jails and municipal prisons in the United States, and 187,791 to hospitals for the insane. The total number of persons reported as actually confined in prisons, penitentiaries, county jails and institutions for the care of juvenile delinquents on January 1, 1910, was 136,472. The statistics for the State of New York showed that her total prison population was on September 30, 1908, 18,454 and on September 30, 1914, 20,185. In addition there were persons convicted of crime but released on probation, children, on September 30, 1908, 730, adults, 1648; on September 30, 1914, children, 2784, adults, 8141; These figures were taken from the Eighth Annual Report of the State Probation Commission. The total number of persons convicted of crime in the State of New York and either in prison or conditionally released on probation or parole on September 30, 1914, was 32,493. The total cost of maintenance of the State prisons, adult and juvenile reformatories and penitentiaries (not including county jails) was in 1914, $2,951,940.42. The average daily population was 13,440. The average *per capita* cost of maintenance was $219.63. The average number on probation, 1914, was 9,434. The entire estimated cost of probation in 1914 was $206,978.63. The average *per capita* cost was $21.94. In considering the problem suggested by these figures Mr. Wickersham said that they were confronted with the question, "What is crime and who are criminals?" Dr. F. H. Wines in his book on "Punishment and Retribution," said, "Crimes are wrongful actions, violations of the rights of other men, injuries done to individuals or to society, against which there is a legal prohibition enforced by some appropriate legal penalty." The New York Penal Law defined "crime" as "an act of omission forbidden by law, and punishable upon conviction by: (1) death; or, (2) imprisonment; or, (3) fine; or, (4) removal from office; or, (5) disqualification to hold any office of trust, honor or profit under the State; or, (6) other penal discipline." The criminal was a "man who put himself in an attitude of antagonism to the law." He was the man who did something the law said he must not do, or failed to do something the law commanded him to do. One of Judge Olson's associates in the Municipal Court of Chicago, Judge Gemmill, had pertinently suggested that "In discussing the question: 'Who is the criminal?' we must not lose sight of the fact that the majority of the persons brought into our criminal courts to-day are not criminals primarily because of what they have done, but because we changed our ideas of the relation of the individual to society and the State." For instance, the enforcement of the Pure Food Law had created criminals in that many who had carried on certain practices for years suddenly, when the new law went into effect, found themselves in antagonism to it.

The condition of the State prison at Sing Sing had been a disgrace to the State for years. Mr. Osborne's wonderful work in Sing Sing had introduced a new hope, a new atmosphere, among the prisoners, but so long as those vile, unsanitary, archaic buildings were maintained by the State, his work would be sorely handicapped. The prison at Sing Sing should be abandoned and pulled down. The State Commission on Prison Reform had recommended that it be abolished and that a new prison be provided without delay, within a convenient distance from New York City. Every day that was delayed was a disgrace to the State. The State prison at Auburn was not much better. The system of building prisons with small cells, and maintaining old prisons of that type, without sanitary conditions, was in effect the creation and maintenance by the State of breeding places for crime and disease. They were merely places maintained by the State to manufacture crime and insure the perdition of all who were confined within them. The condition of many of the county jails was even worse than that of the State prisons. The prisoners in the penitentiaries were maintained in idleness, there were no schools for the illiterate; there was no class instruction and comparatively little industrial employment. The significance of the problem of crime to society lay in the fact that unless the criminal was led to forsake the evil of his ways, society was charged with a continuous responsibility for him and his. The primary concern of society in its relation to crime was to prevent the commission of crime, just as the primary purpose of medical science was to prevent disease. Mr. Wickersham said that the old theory of retribution or vengeance in the punishment of crime had given way to the theory of reformation and prevention. In this, society had made great progress; but uneven progress. So long as their State prisons and their county penitentiaries and jails remained what they were, they could hardly claim to have done more than to become awakened to the uneasy sense of civic injustice in dealing with the problem. But the time had certainly come when, to use the language of the invitation of this meeting, the law and medicine should join hands to form a constructive program, aiming to do for crime, what had been done for disease through systematic study and classification, leading up to effective measures of prevention and intelligent individual treatment.

The Progress That Has Been Made and What the Future Promises, as Shown by the Psychopathic Laboratory.—Judge HARRY OLSON, Chief Justice of the Municipal Court of Chicago, read this paper. He said that insanity, feeble-mindedness, and mental deficiency were on the increase in this country. Many factors contributed to this result, among which first came to mind the speed of their civilization, the inadequate immigration exclusion laws, the disregard of the law of eugenics, the relation of specific disease to heredity and mental health, and to these might be added the conservation of the defective classes brought about by higher standards of civilization. Had the increase of mental defectives any relation to the commission of crime, He thought it had. During ten years' experience as a public prosecutor in the Criminal Courts of Cook County the fact was constantly impressed upon him that large numbers of the criminal classes were defective to the extent that their defect was the cause of their criminality, and especially was this so of many offenders of adolescent age. The first fact that attracted his attention was the uniformity in the number, character, and conditions of crime. For instance, in Chicago, the aggregate number of arrests for felony for the year 1914 was 8673, for the preceding year, 8102, for the year before that, 7362, and if they ran back for a number of years they would find that the number of arests was as uniform, proportionate to population, as the number of marriages and births. This same uniformity existed in all countries and all degrees of civilization. If they were to look into the character of crime for which convictions were had, they would find a like uniformity. The static character of criminal statistics in relation to population the world over, the fact that the criminal age, when first commitments occurred, appeared early when responsibility came, ranging from 16 to 24 years, and that only 2 per cent. of the population were ever charged with crime, always impressed him as significant facts pointing to something inherently defective in the race. The investigation and research of the alienist and the psychologist tended to confirm this belief. Thus far little or no impression had been made on the static existence of crime by their efforts, through punishment and prevention, and one would have supposed that this fact alone would have directed those vitally interested in this subject, such as jurists, sociologists, etc., to check themselves up and cast a critical glance over the past and into other directions for the future. They must adopt new methods, the modern methods of the medical profession, diagnosis and treatment, if cure was impossible. Medical science had advanced, but the law had lagged behind. Until a few years ago

very little instruction was imparted in the medical schools in psychology and psychiatry. The financial rewards were not inviting in this field, nor were the prospects of successful achievement on a par with the opportunities in internal medicine or surgery. If the ordinary physician had lacked interest in the subject, what must be said of the lawyers and the judges? Unless a large fee were involved the lawyer gave no attention to the subject. Their judges had little knowledge of psychiatry, sociology, anthropology, or the significance of criminal statistics, and, if they were to judge solely by the legal test for insanity prevalent in most of their States, the medical profession was about 73 years in advance of the legal profession. The courts were beginning to rely more upon the opinions of medical men than formerly. The institution of phychopathic laboratories in connection with courts was an indication that the legal profession was beginning to appreciate that a large number of chronic offenders were not always benefited by the legal punishment which was inflicted with the three classic objects in view: First, retribution; second, intimidation, and third, reformation. The idea of punishment for a deed presupposed responsibility. They were learning that many of the criminal insane and feeble-minded on whom legal punishment had been inflicted in their courts were not fully responsible and their punishment did not work their reformation. The first psychopathic laboratory in connection with courts in this country was that instituted through the beneficence of Mrs. William F. Dummer of Chicago in the Juvenile Court of that city in 1908. The tests in the Psychopathic Laboratory for feeble-mindedness and insanity were the Rossolino, Binet-Simon, graduated association, analysis synthesis tests, and the standard tests used in practically all the psychiatrical clinics of Europe, as well as physical, pychological, and other examinations. As a result of the work of the laboratory of this court in demonstrating the preponderant rôle which feeble-mindedness was playing in the causation of crime, especially of fundamental crime, they had been able to have a bill passed in Illinois which did for the feeble-minded delinquent what the insanity laws had been trying to do for the insane. This was a very big step forward in the solution of the crime problem. They were finding that many of the common crimes were due to feeble-mindedness, moral defect, the insanities, especially dementia precox in its various forms, the cretinoids, spileptics and psychopathic constitutions. These cases, of course, were not cured by imprisonment in jails or penitentiaries. What was the promise for the future? The feeble-minded situation as a whole was a hopeless one. The only present methods of handling the situation were isolation and sterilization, since they realized more and more, daily, that the vast majority of these cases were of a hereditary nature. The farm colony offered the one solution for the treatment of the defective delinquents who got into the courts. The psycopath, the precox case, when taken in the early years and given proper training, could undoubtedly be helped. The feeble-minded should be sorted out and new methods of training evolved. The courts of their large cities must meet the responsibilities thrown upon them by the discoveries in science by instituting psychopathic laboratories, so that the criminal defective might be identified. If followed by legislation permitting the segregation of the defective classes who needed such care, they would make a substantial advance in controlling crime. In order to win the war against crime and mental deficiency they must educate medical men who could lead. Judge Olson presented a résume showing the average chronological, basal, and mental ages of the different groups, with their average per cent. of arrest in the Boys', Juvenile, and other courts; also the number of cases having complications such as dementia precox, alcoholism, etc.

The Part Which Penal Institutions Might Be Made to Play in the Solution of the Problem.—Mr. THOMAS MOTT OSBORNE, Warden of Sing Sing prison, delivered this address. He said that in answer to the question on the program, as they might have anticipated, his reply was in the affirmative "yes," the time had come when ethics, the law, and medicine should join hands to form a constructive program leading to effective measures for the intelligent treatment of the criminal. It had been pointed out that the prison should be very much like the hospital in its study of the individual and the application of remedial measures, but it should also have been pointed out that when the time came to make that reform, it would be found that it would not be highly regarded in political circles, where any plumber or saloon keeper was thought to be suitable for such distasteful work. When someone attempted such a reform he would find that he had committed an unpardonable sin only to be wiped out by a possible indictment. When he went into prison work two years ago, he went into Auburn prison on the same footing as a prisoner with the idea of getting as near as possible the criminal's point of view. From his experience he said he felt convinced that the court was not the place to hold a clinic for criminals; in fact it was the very last place to study the criminal for he was under a peculiar strain, believed the court was his enemy, and it was impossible under those circumstances to get him to tell the truth. He suggested that all reforms belonged to the prison rather than to the court. At Auburn he tried to get at the bottom of the trouble, looking at the problem without prejudice and with the hope of gaining a grain of truth. He had learned something of the attitude of the criminal. He had heard many men speak on prison work, and everyone had shown absolute ignorance of the standpoint of the prisoner. Unless one had seen the inside as well as the outside of the prison cell, he was in no position to talk on this subject. In fact every warden and district attorney should be sent to prison as a prisoner for a while before he was permitted to occupy his position. Along with the question as to how they were to deal with the criminal came the question, "What is criminal?" They should demolish the idea that the criminal was a different creature from other men. Mr. Osborne said he had known dozens of men in State's prison and been with them in the closest association day after day and month after month, and to make the association even nearer he went to the road building camp where he worked and played and lived with the men for three months. Those men had been guilty of all sorts of crimes and were from all classes of society. The result of his experience could be briefly put in this way: The first cause of crime was human nature and the way in which human nature worked under the conditions in which these men had been placed. Just how much importance could be given to heredity and how much to environment he could not say. His former belief in heredity, however, had been much modified since he had worked in the prison and in the Junior Republic. The conditions at Sing Sing had been frequently described and redescribed, yet there were certain phases of the matter that his friends of the daily press had insisted on forcing on their attention and which they had not always viewed from the proper angle. The prison was a dumping ground for convicted men, no matter what kind of a man he was or what kind of a disease he might be afflicted with. They had never segregated those men who had venereal diseases until within the last few months. They all used the same dining room and no attempt was made to prevent the communication of infection. As for the cells, it was difficult to describe these horrible, damp cells, eight feet high, seven feet long, and three feet three inches wide. He asked if they could imagine what must be the physical and the mental condition of anyone staying in such a hole all day every Sunday and every holiday. The close confinement in such a place for such a length of time furnished the explanation of the fact that assaults were very common on Monday and also attempts at suicide, and helped to explain why masturbation was very common. The conditions of labor were bad, the shops were dark, crowded, and unsanitary. Then the system of silence with the method of surveillance imposed a horrible mental strain. In spite of all the watching vice was rampant no matter how closely the men were watched, and acts of vice took place right under the eyes of the keepers. The same thing was formerly true of the drug traffic. There was no drug traffic in Sing Sing to-day. For five years the prison records showed only two punishments for sodomy, but did they suppose there was no sodomy during that time? The truth was that this vice was very common, but no attention was paid to it. It was never punished and the consequence was that the prison became a sink of vice of which most people had absolutely no conception. Another rule was that a man in solitary confinement was allowed only one gill of water with one slice of bread, and when a keeper had a grudge against him he would take a nail and put a hole in the tin cup and thus deprive the man even of his gill of water. Men had been

known to be driven to such desperation by lack of water that they would drink from their pails. They had made some reforms such as the change in the management of the guards who had been working in unequal shifts, giving them a steady eight hour shift; they had succeeded in having prisoners afflicted with venereal diseases placed in a company by themselves. In keeping the men out of the cells they were protecting them from tuberculosis and the community to that extent. The idea of making prison a place so attractive that men would want to break into it was not a new one. The men were now allowed to talk in the mess hall and in the work shops. It was through sin and suffering that some of them found redemption, but did anyone think that sending a sinning man to White Plains would do him any good? One might just as well take a patient and hit him with an ax to cure his disease as to take many of these men to White Plains. They had done some splendid work at Sing Sing and when he saw the very foundations of it destroyed, did they think he was going to keep quiet? Far from it. He said he was going to raise his voice so that it would be heard over the whole State. What did the Grand Jury at White Plains know about the delicate adjustment of discipline and that it was founded on truth, on telling the truth, and there was the stumbling block. He did not object to having Sing Sing investigated, but until every man and woman in the State knew what was there and what the problems were, it would be of little use. He would be very glad to have an investigation, but not a dishonest or an incomplete investigation. Conditions at Sing Sing were infinitely better than they were a short time ago under the old system. He had not made any rules about "dope." He only made a few suggestions and then waited. The drugs had disappeared by the action of the men themselves. One package was thrown into the river, and others were disposed of and the drugs just stopped coming in. In closing Mr. Osborne said that no man wanted to get sick purposely so that he could go to a hospital, and no one broke his leg to get into a hospital, but if such an accident did happen to him he was glad of the opportunity to go to a hospital. So if a man found that he needed prison treatment he would prefer to go to a good one, and that prison ought to be the best where the man got the particular training he needed, precisely as he got suitable treatment in a hospital. He thought that the State's prison would be a tremendous help in the study of crime and for turning the destructive forces in society into constructive forces, but he did not know what the end would be.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

State Board of Medical Examiners of South Carolina.

June, 1915.

JUNIOR ANATOMY.

1. Describe the liver and give its blood supply.
2. Describe the urinary bladder.
3. Describe the left lung and give its blood supply.
4. Describe the inferior maxillary bone.
5. Describe the formation of the brachial plexus.

SENIOR ANATOMY.

1. Name the blood vessels and nerves encountered in ligation of the brachial artery in the middle of the arm, giving their positions in relation to the artery.
2. For what anatomical reason should wounds of the scalp be closed loosely?
3. Where is the pain located when the maxillary division of the fifth nerve is affected?
4. When sarcomata wander from the seat of primary growth, where do they appear and why?
5. Describe the space that should be selected for doing a paracentesis of the pericardium and give your reason for this selection.
6. With pus beneath the thick middle portion of the palmar fascia, name the points at which the abscess is liable to point.
7. How is collateral circulation established after ligation of the common carotid artery.
8. With a hemorrhage into the pons below the point of decussation of the seventh nerve, what portions of body will be paralyzed?
9. Where, in the stomach, is carcinoma most apt to occur and why?

PHYSIOLOGY.

1. What is an enzyme? Mention one and describe its action.
2. What important centers are situated in the medulla oblongata?
3. Discuss the lymphatic system.
4. What changes occur in the course of the circulation at birth?
5. Mention the glands of internal secretion. What are the theories in regard to their respective functions?

CHEMISTRY.

1. What is the amount of CO_2 in the atmosphere and why does it not increase?
2. How does ferric hydrate act as an antidote for the poisonous properties of arsenic?
3. What are the chemical properties of HNO_3 and into the composition of what explosive does it enter?
4. What is calcium sulphate? What peculiar property renders it useful in surgery?
5. What are the diagnostic uses of electricity?

MATERIA MEDICA.

1. What preparation of iodine and mercury would you combine for internal use? what is the dose of each?
2. Name two or more preparations of digitalis and give dose of each.
3. Give dose and therapeutic effect of atropine, tr. nux vomica, Fowler's sol., arsenic, fl. ext. ergot, tr. opium.
4. Name a vasodilator, a vasoconstrictor, a hydrogogue cathartic, a cholagogue cathartic, a diuretic, and give dose of each.
5. Write a prescription in compliance with "The Harrison Anti-Narcotic Act" for a cough mixture containing codeine.

THERAPEUTICS.

What drugs would you use in treating the following diseases: Give dose, frequency, and therapeutic effect. If therapeutic agents employed other than drugs tell how they should be used.

(1) Gastroenteritis in child two years old. (2) Measles. (3) Acute catarrhal dysentery in adult. (4) Diabetic coma. (5) General anasarca accompanying cardiac insufficiency. (6) Spasmodic croup. (7) Renal colic. (8) Cholera morbus. (9) Chlorosis. (10) Scarlet fever.

PRACTICE OF MEDICINE.

1. Describe a case of Landry's paralysis: acute ascending paralysis.
2. Give etiology, symptoms, physical signs and possible terminations of pulmonary infarction.
3. Mention the causes of cardiac hypertrophy.
4. Describe a case of acute hemorrhagic pancreatitis, stating the diseases with which it might be confounded. Give their diagnostic differences. What treatment would you recommend for a case of acute hemorrhagic pancreatitis?
5. Mention the characteristic blood findings in (a) pernicious anemia; (b) myeloid leucemia; (c) lymphatic leucemia.
6. Define diphtheria. State its most frequent sequelæ.
7. A man fifty years old complains that he has a cough, dyspnea on exertion, has noticed for the past three months that his feet were swollen at night. What diseases might cause such symptoms? Briefly differentiate the diseases mentioned.
8. How would you recognize dilatation of the stomach? What are the causes and how would you differentiate them?
9. Enumerate the conditions of the kidney which may give rise to an abdominal tumor, and state how you would make your diagnosis as to its nature and origin
10. What are the most reliable physical signs of fluid in the pleural cavity?

OBSTETRICS.

1. Name the fetal envelopes from without inward.
2. Describe the vitellus, the allantois, the amnion and its contents.
3. Describe the development of the placenta.
4. As pregnancy progresses state the important

changes, physical and mental, that occur, or may occur, in the disposition and organism of the pregnant woman.

5. Describe the gross anatomy of the mammary glands, give the changes which occur in them during pregnancy, and give the management of the glands in case the infant is stillborn or if for any reason nursing is considered inadvisable.

6. Name the varieties of glycosuria that may occur in pregnancy; give their significance and management.

7. Give the etiology, symptoms and treatment of the albuminuria of pregnancy without anatomical kidney lesion.

8. Describe the conditions, mandatory and elective, under which cesarean section is done and give in general terms the method of doing the operation.

9. Diagnose a face presentation, L. M. A. position, and give mechanism and management of the same.

10. Give management of a brow presentation, R. M. P. position.

11. Name and describe the common varieties of obstetric forceps, give general indication for their use, and describe their use in any given condition that you may choose.

12. Summoned to a patient about seventy-two hours into her puerperium, and given a history of a recent chill, and present rise of temperature, with diminution of lochia, name the conditions, one of which is probably present, and differentiate between them.

N. B.—Answer any two of questions 1, 2, 3, and 4. Each of the remaining questions demands an answer.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

STATE BOARD OF MEDICAL EXAMINERS OF SOUTH CAROLINA.

June, 1915.

JUNIOR ANATOMY.

1. "The *liver* is the largest gland in the body, measuring in its transverse diameter from ten to twelve inches, and its antero-posterior six to seven, and its thickest part about three inches, and weighing about from three to four pounds. It occupies the upper part of the abdominal cavity, and the right hypochondriac, epigastric, and a portion of the left hypochondriac regions. Its upper surface is convex and rests against the diaphragm and a small portion of the abdominal parietes in front. Its lower surface is in contact with the duodenum and stomach, the right kidney and suprarenal capsules, and the hepatic flexure of the colon. It is divided by the longitudinal fissure into the right and left lobes. The liver has five fissures, five lobes, five ligaments, five sets of vessels, and is inclosed in a fibrous coat, continuous at the transverse fissure with the capsule of Glisson. It is also invested by the peritoneum, except at the attachment of the coronary ligament." (Young's *Anatomy.*)

The *fissures* are: umbilical, of ductus venosus, of gall bladder, transverse, and for inferior vena cava.

The *lobes* are: right, left, caudate, quadrate, and spigelian.

The *ligaments* are: Falciform, 2 lateral, coronary, round and of ductus venosus.

The *vessels* are: Hepatic artery and veins, portal vein, and hepatic duct.

2. The *male bladder* is a musculo-membranous pouch, situated in the pelvis, behind the pubes and in front of the rectum. It has a superior surface, antero-inferior surface, two lateral surfaces, a base or fundus, and a summit or apex. It is retained in its place by the two anterior ligaments, two lateral ligaments, and the urachus; there are also five false ligaments formed by folds of the peritoneum. Internally, on the floor, is the trigone, between the openings of the two ureters and the urethra. The anterior part of the bladder is uncovered by peritoneum, and is in relation with the triangular ligament, the symphysis pubis, and the puboprostatic ligament. Above it is covered with peritoneum and is in relation with the rectum and small intestines. The base is in relation with the rectovesical pouch, vasa deferentia, and seminal vesicles, all of which separate it from the rectum. It is supplied by the superior, middle, and inferior vesical arteries; and the pelvic plexus of the sympathetic, and the third and fourth sacral nerves.

3. "The lung is cone shaped, with the base downwards. The anex projects upwards into the root of the neck behind the clavicle and anterior scalene muscle. Above the first rib, the first part of the subclavian artery lies in front, being separated from it by the pleura. The base is concave, resting upon the diaphragm, and following the attachment of the midriff is placed lower externally and posteriorly than anteriorly. The outer surface is convex, and corresponds to the chest wall. The inner surface is concave, corresponding in part to the convex outer surface of the pericardium. It presents about its middle, and towards the posterior part, a slit, the hilum pulmonis, where the bronchi and vessels pass in to form the root. The anterior margin is thin, and overlaps the pericardium, and presents on the left side a notch for the apex of the heart. The posterior margin is rounded, and occupies the groove by the side of the vertebræ. The left lung is smaller and narrower than the right, and is divided into an upper and lower lobe by a fissure, which passes upwards and backwards from the anterior border nearly to the root. The root consists of the bronchus, a branch of the pulmonary artery, two pulmonary veins, nutritive bronchial vessels, anterior and posterior pulmonary plexuses, lymphatic vessels and glands, all held together by areolar tissue, and covered by the pleura." (Aids to *Anatomy.*)

Blood-Supply: Left bronchial artery for nutrition.

4. *Inferior maxilla* consists of a body and two rami. The body is horse-shoe shaped and contains the lower teeth; externally it presents the symphysis, mental process, mental foramen, incisive fossa, and external oblique line; internally it presents the four genial tubercles, sublingual fossa, internal oblique line, submaxillary fossa. The alveolar border has sixteen cavities for teeth. The ramus is quadrilateral, and presents the inferior dental foramen and a spine. Above it has the coronoid and condyloid processes, separated by the sigmoid notch. The *muscles attached* are: Levator menti, depressor labii inferioris, depressor anguli oris, platysma myoides, buccinator, masseter, orbicularis oris, geniohyoid, geniohyoglossus, mylohyoid, digastric, superior constrictor of pharynx, temporal, internal and external pterygoids.

5. The *brachial plexus* is formed by the union and subsequent division of the anterior divisions of the fifth, sixth, seventh, and eighth cervical and the first dorsal nerves. The union of the fifth and sixth makes the upper trunk; the seventh forms the middle trunk, and the eighth cervical and first dorsal make the lower trunk. Each of these trunks is divided into an anterior and a posterior branch. The anterior branches, from the upper and middle trunks, make the upper or outer cord of the plexus; the anterior branch of the lower trunk becomes the lower or inner cord; the three posterior branches unite to form the posterior or middle cord. The plexus lies between the Scalenus anticus and medius. The *branches* are: (1) Above the clavicle; communicating, muscular, posterior thoracic, and suprascapular. (2) *From outer cord:* External anterior thoracic, musculocutaneous, and outer head of median. (3) *From inner cord:* Internal anterior thoracic, lesser internal cutaneous, ulnar, and inner head of median. (4) *From posterior cord:* Subscapular, circumflex, and musculospiral.

SENIOR ANATOMY.

1. In ligating the brachial artery in the middle of the arm, the following blood-vessels and nerves are encountered: The basilic vein and internal cutaneous nerve, to the inner side of the artery; the median nerve, crossing the artery from without inwards; the venæ comites, one on each side of the artery.

2. To allow for drainage and to prevent infection from spreading along the emissary veins to the meninges or intracranial sinuses.

3. *Second, or superior maxiliary branch*, supplies sensation to skin and conjunctiva of lower lid, nose, cheek, upper lip, upper teeth and alveolar processes, and palate. *Third, or inferior maxillary branch*, supplies sensation to external auditory meatus, side of head, mucous membrane of mouth, anterior two-thirds of tongue, lower teeth, lower lip and skin of the lower part of the face.

4. Metastasis is allied to embolism; small particles may be carried by the blood vessels or lymphatic channels to neighboring or distant parts of the body where they may lodge in the capillaries. Hence secondary sarcomata may appear wherever the blood vessels or lymph channels are able to carry particles of the original tumor.

5. Paracentesis of the pericardium should be done "in either the fifth or sixth interspace, and either in-

ternal to or external to the internal mammary artery. In the fifth interspace, the width is greater near the sternal border, and is the space usually chosen. In the sixth interspace, the internal mammary artery and the pleura are both further from the left sternal border, and puncture may be made more directly inward. Where sufficient width of space exists, the sixth interspace may be chosen. Puncture should, by preference, be made internal to the internal mammary artery, as the pleura is in less danger of injury, especially in the fifth space—and even in the sixth space, the puncture would have to be about one inch outside of the border of the sternum to be sure of avoiding the internal mammary artery, and then it is apt to strike the pleura." (Bickham's *Operative Surgery.*)

6. With pus beneath the thick middle portion of the palmar fascia, the abscess is liable to point above the clefts of the fingers, on the dorsum of the hand, or in the forearm.

7. After ligation of the common carotid artery, the collateral circulation is carried on as follows: "(1) Branches of the external carotid on the side tied, anastomosing with the corresponding branches of the opposite side, viz., (*a*) Facial with facial; (*b*) temporal with temporal; (*c*) occipital with occipital; and (*d*) superior thyroid with superior thyroid. (2) Anastomoses between the internal carotids of opposite sides through the anterior segment of the circle of Willis—anterior cerebral of one side with the anterior cerebral of the other, through the anterior communicating. (3) Anastomoses between the subclavian and the external carotid of the side tied, viz., (*a*) The deep cervical with the princeps cervicis of occipital; (*b*) the vertebral with the occipital; (*c*) inferior thyroid with superior thyroid. (4) Anastomoses between the subclavian and the internal carotid of the side tied, the vertebral through the basilar and posterior cerebral with posterior communicating from internal carotid. (5) Anastomoses of the ophthalmic, from the internal carotid with branches of the external carotid on the side tied, viz., (*a*) Nasal of ophthalmic with angular of facial; (*b*) infraorbital, from internal maxillary, with twigs of facial; (*c*) supraorbital and frontal, from ophthalmic, with terminations of the anterior temporal." (McLachlan's *Applied Anatomy.*)

8. Hemorrhage into the pons below the point of decussation of the seventh nerve will result in a crossed hemiplegia, there will be facial paralysis on the same side as the lesion, and paralysis of the extremities on the opposite side.

9. Carcinoma of the stomach is most apt to occur at or near the pylorus, because that is the most common site of gastric ulcer, and gastric carcinoma is most frequently found to develop in an old gastric ulcer.

PHYSIOLOGY.

1. An *enzyme* is a body produced by a living organism or cell and is capable of effecting certain chemical changes in certain bodies without itself undergoing alteration in the process. An amylolytic enzyme, such as the amylopsin of the pancreatic juice, by a hydrolytic cleavage of the starch molecule, converts polysaccharides into dextrose and maltose.

2. The *medulla oblongata* contains collections of gray matter which serve as special nerve centers for the following functions or actions: respiration, salivary secretion, mastication, sucking, deglutition, vomiting, voice, facial expression; it also contains the cardiac and vasomotor centers.

3. The lymphatic system consists of: lymphatic glands, lymph vessels, perivascular lymph spaces, the lymph canalicular system, the pericardial, pleural, peritoneal, and synovial cavities, and the lacteals.

The lymphatic circulation is, strictly speaking, not a circulation at all, since the lymph flows only in one direction, namely, toward the heart. The lymph capillaries take up any excess of the blood plasma which is not required for the nutrition of the tissues. These capillaries consist of a single layer of epithelium, and empty themselves into vessels very like the veins. The lymph vessels are well provided with valves, which are so closely approximated as to give the vessels a beaded appearance. All the lymphatic vessels, except those of the right upper half of the body, empty into the thoracic duct, which terminates in the left subclavian vein, where the left internal jugular vein also enters. Those from the right upper half of the body discharge into the right lymphatic duct, which, in turn, empties into the right subclavian vein at its junction with the right internal jugular vein.

The forces concerned in the circulation of the lymph are: (1) The pressure of the blood in the blood-vessels; (2) thoracic aspiration; (3) muscular contractions of the voluntary muscles; (4) contractions of the intestine; (5) the action of the valves in the lacteals and lymphatics.

The *function of the lymphatic system* is to provide the tissues with material necessary to their functional activity, growth, and repair; to receive from the tissues their waste products; and to convey the products of digestion and absorption to the blood-current.

The lymph capillaries differ from the blood-capillaries, chiefly, in their larger and very variable caliber and also in their numerous communications with the lymph spaces. The lymph vessels in general have thinner coats than the blood-vessels; and the valves in the lymph vessels are much more abundant than in the veins.

4. *Changes that occur in the fetal circulation at birth:* The hypogastric arteries dwindle and close, the foramen ovale becomes obliterated, the ductus arteriosus and ductus venosus become obliterated, the umbilical vein becomes impervious, and the Eustachian valve atrophies.

5. *Internal secretions:* It is generally held now that the glandular organs, chiefly the pancreas, liver, and the ductless glands, produce a secretion, peculiar in each case to the particular gland producing it, and which is supposed to be given off to the blood or lymph, and to have some peculiar value in the general metabolism of the body. Such secretions are called internal secretions, in contradistinction to the previously known secretions, which are carried off by a duct, and are known as external secretions. Very little is definitely known of these internal secretions, but much work is being done on the subject.

The function of the spleen: The following theories have been held: (1) It is a source of production of the white blood corpuscles; (2) it is a source of production of the red blood corpuscles during fetal life; (3) it is a place where the red blood corpuscles are destroyed; (4) uric acid is produced in the spleen; (5) an enzyme is produced in the spleen and is carried by the blood to the pancreas, where it converts the trypsinogen into trypsin.

The function of the thyroid is not definitely settled: (1) it has some trophic function, regulating oxidation in the body, and it is supposed to have also a special influence on the vasomotor nerves, the skin, the bones, and on the sexual functions; (2) it is supposed to antagonize toxic substances and (3) it produces an internal secretion.

The function of the thymus is not settled; it is said: (1) To be a blood-forming organ; (2) to have influence on growth and nutrition; (3) in hibernating animals it is supposed to store up materials which can be utilized during the period of inactivity.

The function of the suprarenals is not definitely settled; they produce an internal secretion which is probably necessary to life; it is supposed that they are able to destroy or remove some toxic substance produced elsewhere in the body.

Function of the pituitary gland: "The *anterior* lobe is concerned with the process of growth, hypertrophy leading to overgrowth of the skeleton, and partial removal to failure of development of the body as a whole and of the sexual glands. Extracts of the *posterior* lobe, when injected into an animal, have a direct action on plain muscle all over the body; they cause constriction of the arterioles and a rise of blood pressure, contraction of the muscular coats of the digestive tract and of the bronchioles, and contraction of the uterus. The extracts also produce an increased flow of urine, which was at first attributed to the presence of a substance having a specific effect upon the renal cells; it is probable, however, that the diuretic effect is merely an indirect result of the more rapid flow of blood through the kidney which follows the injection of the extract. Extracts of the posterior lobe increase the secretion of milk, and after the injection a larger amount of milk is formed by the animal in the course of twenty-four hours." (Bainbridge and Menzies' *Essentials of Physiology.*)

CHEMISTRY.

1. There are about four parts of carbon dioxide in 10,000 parts of air. The carbon dioxide in the air does not increase because it is being constantly removed by the plants, the chlorophyll of which (under the influence of sunlight) decomposes the CO_2, and returns the oxygen to the air.

2. The ferric hydrate changes the arsenic into ferrous arsenate, which is non-poisonous.

3. *Chemical properties of nitric acid:* When exposed to air and light, it is decomposed into N_2O_4, H_2O, and oxygen; a similar result is obtained when it is exposed to heat; it is an oxidizing agent; it destroys many organic substances; in combination with metals, it produces nitrates.

It enters into the composition of nitroglycerin.

4. Calcium sulphate is gypsum, or plaster of Paris. When mixed with water it "sets," making a hard casing; it is used in the fixing of fractures, etc.

5. *Electricity is used in diagnosis* as a means of illumination to be employed with the various "scopes" for examining the cavities of the body. It is also used in determining the reactions of degeneration. "A normal nerve or muscle will respond to any form of electric stimulation. If it is diseased, it will not respond to a faradic current, but will give an increased response to a galvanic current, but the reaction obtained will be slow and sinuous, in opposition to the quick and prompt response obtained when a nerve is normal. The usual method of testing is to first apply a slowly interrupted current to the corresponding normal nerve, and then try the same current on the diseased nerve. If the nerve is completely diseased or sclerosed, no reaction will be obtained to either current. The galvanic current is then tried and a minimum current applied to the diseased nerve first, and the response will be slow and sinuous. The same current applied to the healthy nerve will not cause any reaction, and to obtain a response it will be necessary to increase the current to such an extent that it will be painful. Reactions of degeneration are not obtained until about one or two weeks after the severance of the nerve, and should never be sought for as long as a nerve is inflamed or there is pain on pressure. Its presence makes the prognosis doubtful; its absence, good." (Anders and Boston's *Medical Diagnosis.*)

MATERIA MEDICA.

1. Hydrargyri iodidum flavum. Dose, gr. 1/5; and hydrargyri iodidum rubrum. Dose, gr. 1/20.

2. Fluidextract of digitalis, dose ♏j; extract of digitalis, dose, gr. 1/5; infusion of digitalis, dose, ℥ij; tincture of digitalis, dose, ♏xv.

3. ATROPINE: Dose, gr. 1/160.

Action: Anodyne, mydriatic, inhibits secretions, depressant of terminations of nerves, accelerates the heart beat, causes rise in blood pressure, but toxic doses cause the blood pressure to fall; it stimulates the respiratory center, but large doses depress the same; it may cause vertigo, restlessness, excitement, delirium, or mania.

TINCTURE OF NUX VOMICA: *Dose,* ♏v-x.

Physiological action: Strychnine is a bitter tonic, stimulates appetite, secretion, and digestion, increases peristalsis, stimulates the vasomotor centers, and so raises arterial tension, and stimulates both accelerator and inhibitory nerves of the heart. All the functions of the spinal cord are exalted by strychnine, reflex, motor, vasomotor, and sensory. Large doses cause dilated pupils, irregular and jerky respiration, increased reflexes.

FOWLER'S SOLUTION OF ARSENIC: *Dose,* ♏j-v.

Action: It is a tonic; increases cardiac action, respiratory power, intestinal secretions, and peristalsis; produces edema, itching, diarrhea, epigastric pain, irritable and feeble heart.

FLUIDEXTRACT OF ERGOT: *Dose,* ♏xxx.

Physiological action: Ergot stimulates and causes contraction of involuntary muscle fibers, hence it is a vasoconstrictor, hemostatic, and oxytocic. It is also a cardiac sedative, it raises the blood pressure, it increases peristalsis, and is an emmenagogue.

TINCTURE OF OPIUM: *Dose,* ♏viij.

Physiological action: It is analgesic, hypnotic, diaphoretic, narcotic, a respiratory and cardiac stimulant (later a depressant), it checks most secretions (not perspiration), it stimulates the brain, and contracts the pupil.

4. A *vasodilator:* Amyl nitrite, ♏ij-v (by inhalation).

A *vasoconstrictor:* Strychnine sulphate, gr. 1 64.

A *hydragogue cathartic:* Elaterin, gr. 1 10.

A *cholagogue cathartic:* Podophyllum, gr. viij.

A *diuretic:* Potassium acetate, gr. xxx.

5. ℞

Codeinæ sulphatis, gr. iij.
Ammonii chloridi, ʒj.
Fluidextracti glycyrrhizæ, ʒj.
Aquæ destillatæ, q. s. ad ℥ij. M.
Sig.: One teaspoonful every two hours in water.

MARK TAPLEY, M.D.,
911 West Forty-Fourth Street,
New York City.

Registered Number, 23.

For John Jones (aged 30 years), 846 West 156th Street, New York.

October 26, 1915.

THERAPEUTICS.

1. *Gastroenteritis in child two years old:* Two drams of castor oil as a purgative; cool sponging or bath for fever (if present); give no food, but only boiled water or barley water for twenty-four hours. Subsequently, the diet must be properly regulated.

2. *Measles:* Isolation in a well-ventilated and darkened room; cool sponging or bath for fever; cool water to drink; if a sedative is required one grain of phenacetin may be given every three hours for four doses; if the cough is troublesome, three grains of sodium bromide may be given every three hours; inunction with 5 per cent. ichthyol in lanolin will relieve the itching; as a laxative, a quarter of a grain of calomel may be given every hour for two or three doses.

3. *Acute catarrhal dysentery in adult:* "The treatment consists of rest in bed and liquid diet. Rochelle salt (ʒ 4) or Epsom salt (ʒ 4) should be given to cleanse the bowels thoroughly. Castor oil (ʒ 1) with laudanum (gtt. 20) may be used. Pain is relieved by opium, alone or combined with bismuth subnitrate, cocaine or belladonna. Hope's camphor mixture (ʒ 2) may be administered every 3 hours. The colon may be irrigated every 2 hours with lukewarm water or starch-water containing laudanum (ʒ ½)." (*Pocket Cyclopedia.*)

4. *Diabetic coma:* "The coma is usually fatal, and little can be done to delay the result. Inhalation of oxygen has been thought of benefit, and large doses of sodium bicarbonate and other alkalies have rescued from coma by reducing the acid intoxication. Normal salt solution used by rectal irrigation, subcutaneous or intravenous injection, has proved beneficial, to the extent of delaying coma or temporarily restoring consciousness in a few instances. Sodium bicarbonate in strong solution by intravenous injection, hypodermoclysis or rectal irrigation, is worthy of more extended trial. A quart (liter) of a 1 to 2 per cent. solution may be injected slowly into a vein every six hours in a bad attack; when administered by other methods the bicarbonate should be given in increasing doses up to 100 grams (3.5 ounces) a day, or until the reaction of the urine has become alkaline." (French's *Practice of Medicine.*)

5. *General anasarca accompanying cardiac insufficiency:* "The heart balance is best restored by the administration of some preparation of digitalis such as the infusion, ʒi to ʒiv, the tincture, ♏v to xxx, or the powder, gr. i three times daily. The possibility of nausea following the use of digitalis, especially the tincture, should be remembered. The dose of the drug is best guided by the results it produces. When for any reason digitalis is not applicable, strophanthus, strychnine, caffeine, and sparteine may be given. The venous engorgement and dropsy may be relieved by the administration of small doses of mercury and saline purgatives. The combination of calomel, digitalis, and squill, of each gr. i is especially valuable in this connection. When the dropsy is extreme, tapping or multiple incisions may be required. The extreme and distressing shortness of breath is best relieved by morphine, gr. ¼, and inhalations of oxygen." (Hughes' *Practice of Medicine.*)

6. *Spasmodic croup:* "Place the child in a warm, moist room. In mild cases an emetic dose of the wine of ipecac, half a dram every half hour until vomiting ensues, may be sufficient to give relief. A warm mustard bath aids the result. An enema should be ordered if the bowels have not recently moved. In severer cases a croup tent should be made over the crib and a croup kettle started in which has been placed a dram or two of the compound tincture of benzoin. Emesis should be brought about as rapidly as possible. Antipyrin gr. 3 for a three-year-old child acts as an antispasmodic. If there is cyanosis and serious obstruction intubation may be necessary; however, a smear and culture should be made in these cases to exclude diphtheria. The succeeding day should be spent quietly, a light diet given and the bowels kept open.

If there are adenoids present, these should be removed at a later date." (Chapin and Pisek's *Diseases of Children.*)

7. *Renal colic:* "Pain is relieved by the subcutaneous injection of morphine (gr. ⅛-¼) or of morphine (gr. ⅛) and atropine (gr. 1/60); by inhalation of amyl nitrite, chloroform or ether; or by drop doses of amyl nitrite, etc. Calomel should be administered in gr. ½ dose every half-hour until 4 or 5 grains are taken, followed by citrate of magnesia. Opium may be given with the calomel, or combined with belladonna in suppository. A large warm-water enema should be administered. The warm bath, mustard or turpentine stupes, hot fomentations sprinkled with laudanum, large, light linseed poultices, and friction are grateful." (Pocket *Cyclopedia.*)

8. *Cholera morbus:* Hot turpentine stupes to the abdomen or morphine (gr. ¼) hypodermically may be given for the pain. Salines should be administered to remove the offending particles. Should the salts move the bowels too frequently, give paregoric (5 1) and compound tincture of lavender (5 1) every 3 hours until 2 or 3 doses have been taken. Should the pain and diarrhea still continue, give the "Sun Cholera Mixture" in teaspoonful doses after each evacuation of the bowels.

9. *Chlorosis:* The bowels must be kept open with a saline laxative; fresh air, sunshine, suitable food and exercise are necessary; iron must be administered in some form, such as the tincture of the chloride, ♏x-xv after meals, or 3 or 4 grains of Blaud's mass three times a day.

10. *Scarlet fever:* The treatment is that of infectious fevers in general, and in addition: "1. *Serum treatment.*—Serum from convalescents, injected in doses up to 20 c.c., has sometimes proved successful. Good results have also been obtained with polyvalent antistreptococcic sera (*i.e.* sera prepared from several different strains of cocci). 2. The danger of spreading the disease is greatest during the desquamative period. Isolation must therefore be kept up for at least six weeks from the onset, or till all desquamation and discharges (nasal, aural, etc.) have ceased. 3. A minimum amount of nitrogenous food, to avoid irritation of the kidneys. This caution does not affect milk, which may be freely used. 4. Daily toilet, tepid sponging, or tepid baths. 5. Inunction of oily antiseptic preparations into the skin, to prevent dissemination of the desquamating scales. 6. Examine the urine daily for signs of nephritis. 7. The condition of the ears must be carefully watched." (Wheeler and Jack's *Handbook of Treatment.*)

PRACTICE OF MEDICINE.

1. *Landry's paralysis* (acute ascending paralysis) "is an acute disease characterized by palsy, beginning in the feet and ascending to other muscles of the body, finally involving the medulla. Pain and trophic disturbances are absent. The reflexes are diminished or absent, but the muscles do not waste, and the sphincters are not involved. The affection is rare and occurs most often in young male adults. The etiology and pathology are obscure. The onset is sudden and the course acute, terminating usually in death within a week, occasionally being prolonged three or four weeks. The treatment is unsatisfactory." (Hughes' *Practice of Medicine.*)

2. PULMONARY INFARCTION. *Etiology:* It is generally due to embolism or thrombosis of a branch of the pulmonary artery. *Symptoms:* Dyspnea, dilated pupils, livid face, pleuritic pain, hemoptysis, rapid and irregular pulse; embolism of the main artery causes sudden death. *Physical signs:* None characteristic; there may be dullness on percussion, breath sounds may be feeble or harsh, and there may be crepitant or crackling rales. *Possible terminations:* The circulation may be reestablished and the blood removed; gangrene; fibroid patch, or sloughing may result; death.

3. *Causes of cardiac hypertrophy:* Obstruction to the outflow of blood such as results from valvular disease of the heart, emphysema, Bright's disease, and arteriosclerosis; excessive functional activity, such as is produced by prolonged muscular exertion, exophthalmic goiter; excessive use of tea, coffee, and tobacco.

4. *Acute hemorrhagic pancreatitis* is a disease which generally attacks adult males; it is of sudden onset, and the patient suffers intense abdominal pain; vomiting, and epigastric tenderness are also present. Collapse follows, and the patient usually dies in a few days. Medical treatment is of no avail, and surgical treatment offers but slight hope. With regard to *diagnosis,* Anders and Boston state as follows: *Summary of Diagnosis.* In all cases the diagnosis is made with difficulty, the symptoms of hemorrhagic pancreatitis closely resembling those found in other pathological abdominal conditions. The age of the patient (after middle life), the history of previous dyspepsia or of diabetes, and a possible history of traumatism to the abdomen are of considerable importance. Most characteristic, however, is the sudden onset, the deep seated epigastric pain followed by nausea, vomiting, and circulatory collapse. Cammidge's reaction and the presence of fat in the feces are also to be considered.

Differential Diagnosis. Obstruction of the Bowel: When the obstruction occurs in an aged person, the distinction is made with difficulty. (*a*) Acute intestinal obstruction is more common in the young than in the aged, and the pain is less definitely localized than that of pancreatitis. (*b*) Abdominal distention is more marked in intestinal obstruction. (*c*) Fecal vomiting, a characteristic feature of obstruction, is absent in acute hemorrhagic pancreatitis. (*d*) The temperature is normal at the onset, but soon becomes subnormal in obstruction; (*e*) indicanuria is a somewhat constant symptom in obstruction.

Acute Gastroduodenal Catarrh: (1) In this condition there is a distinct rise in the temperature at the onset. (2) The symptoms are not sudden and the pain is of a different character, not deep seated or localized, as is the case in acute inflammation of the pancreas. Cammidge's reaction is negative, as is also an examination for fat in the feces. There is not the same degree of prostration and as marked a tendency toward circulatory collapse as are characteristic of acute pancreatitis.

5. In *pernicious anemia* there is a great diminution in the number of red corpuscles; they may fall to half a million per cubic millimeter; the hemoglobin is also diminished, but not in proportion to the corpuscles, so that the color index is above unity. Poikilocytes, microcytes, macrocytes, normoblasts and megaloblasts may be found. There is no leucocytosis.

In *myeloid leucemia,* there is an enormous leucocytosis, with an increase of eosinophiles; mast cells are present, and myelocytes are present in large numbers. There is some diminution of hemoglobin and of number of red corpuscles.

In *lymphatic leucemia* there is an enormous leucocytosis involving the lymphocytes only, which may be even 90 per cent. of the total leucocytes; there are no myelocytes, but there may be a few nucleated red corpuscles.

6. *Diphtheria* is an acute, infectious, and contagious disease caused by the *Bacillus diphtheriæ,* and characterized by the formation of a fibrinous exudate on a mucous membrane and by constitutional manifestations of toxemia. The *most frequent sequelæ* are: Paralysis (of palate, muscles of eye, face, and larynx); also cardiac and vasomotor paralysis; nephritis may also follow the disease.

7. The symptoms might be caused by cardiac weakness or disease or by renal disease. In the former case the edema begins at the feet and extends upward, and physical examination will show enlargement of the heart or murmurs. In the case of renal disease the edema begins in the face and extends downward, and an examination of the urine may throw light on the exact nature of the disorder.

8. *Dilatation of the stomach* is recognized by the characteristic vomiting occurring at intervals of several days, when large quantities of stagnant fluid and scraps of partially digested or undigested food are ejected. The vomitus is acid, and contains the *Sarcina ventriculi;* on standing, it separates into layers. The outline of the stomach (when distended) may be observed, and splashing sounds may be obtained.

The condition is due to stenosis of the pylorus, pressure on the pylorus from tumors or gallstones, kinking of the pylorus, atony.

If a tumor is found at the pylorus, atony may be ruled out. Cancer will give cachexia, and the presence of the tumor may be detected by palpation; gallstones will give colic and jaundice.

9. The abdominal tumor may be due to floating kidney, hydronephrosis, pyonephrosis, cancer or other tumor of the kidney.

Floating kidney is accompanied by severe attacks of pain, chills, Dietl's crises.

Hydronephrosis may give few symptoms beyond dragging pain, and pressure symptoms.

Pyronephrosis shows pus in the urine, and fever.

Tumor of the kidney may give pain, emaciation, hematuria.

10. *Fluid in the pleural cavity:* There is imperfect expansion on the affected side, the intercostal spaces may bulge, the apex beat may be displaced; percussion shows dulness or flatness, which is movable (according to the position assumed by the patient). The best sign is the presence of the fluid on inserting an aspirating needle.

OBSTETRICS.

1. *The fetal envelopes from without inward:* Decidua, chorion, and amnion.

2. The *vitellus* is the yolk or germinal part of the ovum together with the substance intended for the nutrition of the embryo. The *allantois* is a fetal membrane developing from the lower part of the alimentary canal very early in fetal life; it enters into the formation of the urinary bladder and also of the umbilical cord and placenta.

The *amnion* is the innermost of the fetal membranes; it surrounds the fetus and is continuous with it at the umbilicus; it secretes the liquor amnii, and forms the sheath of the umbilical cord.

The *liquor amnii* consists chiefly of water, but contains small amounts of albumin, epithelial cells, urea, phosphates, chlorides, etc. Its specific gravity is about 1.001 to 1.008. Its source is unknown; it is probably derived from the amnion, by transudation from the maternal vessels of the placenta.

3. *Development of the placenta:* "The placenta, as a separate organ, dates from the third month of pregnancy. At this time the chorion villi atrophy over the whole periphery of the ovum, except at the point where it comes in direct relation with the true mucous membrane of the uterus—the decidua serotina. Here the villi take on an extraordinary growth, forming buds of epithelial cells (syncytium) upon their surface, which rapidly take on the shape of new villi, thus sending out branches in every direction, into each of which a loop of blood vessels is projected. Separating the villi from one another, and dipping down to the base of the chorion between the parent stems of the villous projections, are processes of the decidua, carrying capillary loops of maternal blood vessels. Very early in the history of the ovum the arterioles of this system open directly into the intervillous spaces of the placenta, so that the placental villi are bathed directly in maternal blood. . . . It is now well established, that the placental villi imbed themselves in the soft interglandular substance of the decidua serotina, often projecting into the mouth of the small veins, and that the connective tissue cells multiply and hypertrophy around them (decidual cells). The epithelium of the uterine mucous membrane disappears, except in the glands. The chorion villi are at first covered with two distinct layers of cells; an inner layer composed of single large nucleated cells arranged side by side with distinct cell walls (Langhans' layer), and an outer layer or band of protoplasm in which are imbedded nuclei at irregular intervals (the syncytium). Both of these layers are derived from the chorion and not from the uterine epithelium or the endothelium of the uterine blood vessels. Early in embryonal life (the third month) the Langhans layer disappears and the syncytium remains as the sole epithelial covering of the villi. In the youngest ova yet observed the trophoblast contains lacunæ to which blood is conveyed from the maternal circulation by little curling arteries that wind their way up through the decidual cells to empty directly into the placental sinuses. These arteries are provided with only a delicate endothelial wall. . . . The syncytial cells of the latter have the power to penetrate the endothelium of the decidual arterioles and thus open a direct communication between the placental villi and the maternal blood. By this anatomical arrangement the fetal and maternal blood is, of course, kept separate. The former circulates within the capillary system of the villi; the latter bathes the exterior of the villi." (Hirst's *Obstetrics.*)

4. As pregnancy progresses the *uterus* becomes larger in every way, is more vascular, first sinks and then rises; the cervix becomes more vascular, softer and edematous; later the cervix becomes shorter; *vagina* and *vulva* become hypertrophied, more vascular, discolored and secrete more freely; the vulva becomes more patulous. The *blood* is increased in quantity, chiefly the fluid part and the fibrin making elements; the red cells and hemoglobin are relatively decreased, though absolutely increased; the white cells are increased. The changes in the *breasts* are described in the next answer. The *heart* is more rapid, and the rhythm and rate more easily disturbed. The *lungs* are compressed, their capacity decreased, and the breathing becomes more thoracic. There is increased secretion of saliva, indigestion, vomiting in the morning, and tendency to constipation. The *urine* varies in quantity, and may contain albumin; micturition is more frequent. The woman's *weight* increases; the *skin* becomes pigmented, chiefly on breasts, abdomen and genitals; the *teeth* may decay; the nervous system becomes more irritable and unstable, and neuralgia is apt to occur. There is apt to be change in the woman's disposition.

5. "The mammary glands are compound racemose glands, and consist of gland-tissue which is made up of lobes, and these again of lobules. The lobes are connected by fibrous tissue, and between them is fat. Each lobule is composed of sacculated alveoli and a duct, the lobular duct. The lobular ducts discharge into larger ducts, which in turn discharge into a lactiferous duct, which may be regarded as the excretory duct of a lobe. Of these ducts, there are from fifteen to twenty; and they open at the surface of the nipple. Under the areola the tubuli lactiferi are dilated, forming ampullæ, in which, during the period of lactation, the milk accumulates in the intervals of nursing. The walls of the alveoli consist of a basement membrane, covered, during the period when the gland is not active, by a single layer of flat or cuboidal cells with one nucleus and presenting a granular appearance." (Raymond's *Physiology.*)

During pregnancy the mammary glands increase in size, fulness and firmness; Montgomery's follicles become pronounced; the primary areola becomes larger and darker; the secondary areola appears; the nipple becomes larger, more prominent and more erectile; and colostrum may be expressed.

If the infant is stillborn, or nursing is inadvisable, the mammary glands should be anointed with a solution of atropine sulphate in glycerin (about 1:500); a snug binder should then be applied; the patient should be restricted to as little fluid as possible, and should receive salines to produce watery stools.

6. *Glycosuria in pregnancy:* "Sugar may be found in the urine of pregnant women in from 5 to 25 per cent. of cases after the fifth month or so. It is important to realize that there are other conditions besides diabetes which may account for this. The following four conditions may be distinguished: (1) Diabetes mellitus; (2) Lactosuria; (3) Alimentary; (4) "Idiopathic" Pregnancy Glycosuria. *True Diabetes* must be diagnosed where the condition existed prior to pregnancy, or where the glycosuria is accompanied by symptoms such as polyuria, emaciation, etc. It is a very grave complication of pregnancy, leading in many cases to premature labor, and in about a quarter of the cases to the death of the mother from diabetic coma either during pregnancy or very soon after delivery. The fetus in many cases is born dead. *Lactosuria.* If the urine gives a reaction to Fehling's or some other simple test for sugar, steps should at once be taken to find out whether the sugar is glucose or lactose. This can be done by the polariscope or the fermentation test. In the majority of cases it is lactose, reabsorbed from the milk in the breasts. In the same way lactose is found in the urine of puerperal women who do not nurse. Lactosuria is of no significance. *Alimentary Glycosuria.* This is apparently more easily induced in pregnant than in non-pregnant women. A diminution in the carbohydrates in the diet will probably lead to its disappearance. *Idiopathic Pregnancy Glycosuria.* Under this head are included unexplained cases of glycosuria in pregnancy, unaccompanied by any symptoms, and unaffected by diet. The sugar is rarely present in any quantity, and disappears shortly after labor. It is probably due in some way, not yet understood, to the altered balance in the secretions of the ductless glands." (Johnstone's *Textbook of Midwifery.*)

7. "*Albuminuria* in small amounts, at irregular intervals, has been regarded as physiological on account of its frequent presence without apparent unfavorable symptoms. The anatomical basis for this has been supposed to be the so-called pregnancy kidney, which has been described as a congestion from the pressure of the altered circulation. The safer position is to assume that any amount of albumin is pathological, provided we have the assurance that it is not due to the admixture of discharges from the external genitals. Its clinical significance may be unimportant in some

cases. The amount is generally small, not even appearing in some of the severest types until late in the disease. This may be true even in the later months in the form that terminates in *eclampsia*, in which it may suddenly appear as the attack begins. In such cases daily and even hourly examinations may be necessary."—(Jewett's *Obstetrics.*)

Eclampsia is an acute morbid condition, occurring during pregnancy, labor, or the puerperal state, and is characterized by tonic and clonic convulsions, which affect first the voluntary and then the involuntary muscles; there is total loss of consciousness, which tends either to coma or to sleep, and the condition may terminate in recovery or death. About 75 per cent. of the cases occur in primiparæ. "*The treatment of the attack* consists of the administration of chloroform by inhalation, chloral hydrate (gr. 60) by enema, and the fluidextract of veratrum viride hypodermically (gtt. 15 followed by gtt. 5 repeated frequently enough to keep the pulse at about 60 beats a minute), to control the convulsions, and free purgation by croton oil (gtt. 2, or 3, in sweet oil or glycerin), free sweating by the hot pack, and sometimes depletion by venesection to eliminate the poison. The after treatment consists of free purgation by the salines, restriction of diet, and later the administration of tonics and stimulants. The obstetric treatment is usually noninterference."—(*Pocket Cyclopedia.*) Sometimes *accouchement forcé* is indicated.

8. *Cesarean section.*—"*Indications:* The cases in which it is performed are: (1) Extreme deformity of the pelvis, in which delivery by forceps and version is excluded, and in which craniotomy is either impossible or would be more dangerous to the mother than cutting into the abdomen and uterus; and in which there is not room for a successful symphyseotomy. Such cases present the '*positive*' indication for cesarean section; there is nothing else to be done. Flat pelves having a conjugata vera of 2¼ inches or less, and justo-minor pelves with a conjugata vera of 2½ inches or less, present this positive indication; (2) cases of more moderate pelvic contraction in which craniotomy is possible, but cesarean section is agreed upon to *save the life of the child;* (3) mechanical obstruction in the pelvis from fibroid, cancerous, bony, or other tumors which cannot be pushed up out of the way or be safely removed; (4) irreducible impaction of a *living* child in transverse presentations; (5) in women dying near the end of pregnancy the child, if alive, is rapidly delivered by *post-mortem* cesarean section; (6) various other obstructions from inflammatory adhesions, atresia, constrictions, etc., of the vagina, and uterine displacements, may rarely require the operation; (7) recently the operation has been done in eclampsia cases, where more conservative methods of rapid delivery were impracticable; and (8) in placenta prævia, chiefly with a view to lessen the infant mortality attending the usual treatment of this complication."—(King's *Obstetrics.*)

Cesarean section.—"Fuidextract of ergot, ℥xx, is injected into the thigh muscles just as the anesthesia is begun. The operator assures himself that there is no loop of intestine between the uterus and abdominal wall, beneath the field of incision. Should a coil of intestine be found there, it is pushed above the fundus. An assistant holds the uterus in central position. The skin incision extends one-third above and two-thirds below the level of the umbilicus. It is best made through the right rectus muscle. The external layer of the rectus sheath is divided, the muscular bundles separated with handle of scalpel and the fingers, and the deep layer of the sheath and the peritoneum divided after lifting them with tissue forceps. Bleeding vessels are controlled by gauze sponge pressure or held by catch-forceps before opening the peritoneum. A short longitudinal median incision is made in the uterine wall beginning at the fundus, avoiding the membranes if still unbroken. This is extended downward with fingers, scissors, or scalpel to a total length of about six inches. The hand is thrust through the membranes and the child is extracted by the head or the feet, whichever is most accessible. In case of anterior implanation of the placenta, usually the hand may best be passed directly through it. The cord is clamped at two points with catch-forceps, cut between them, and the child is passed to an assistant. The uterus slips out of the abdomen as the child is extracted, and the intestines are kept back with hot sterilized towels placed over the upper part of the incision. The coverings help also to protect the peritoneum from soiling. The uterus is wrapped in hot moist cloths. As a rule, it is better not to wholly eventrate the uterus. The placenta, if not spontaneously separated, may be peeled off by grasping it with one hand like a sponge. If the cervix is not sufficiently open for drainage, a large rubber tube or gauze strip is passed down through it and withdrawn from below. Irrigating or mopping the uterine cavity is unnecessary. Asepsis is promoted by leaving it as nearly as possible untouched. The peritoneum is sponged dry with the least possible friction or handling. The uterine wound is closed with deep No. 2 chromated catgut sutures at intervals of about 1/3 inch. They are given a wide sweep laterally through the muscular wall, falling short of the decidua. The peritoneal coat of the uterus is closed with a No. 1 continuous plain catgut suture, forming a welt over the deep suture line. The hemorrhage is inconsiderable and usually ceases with the introduction of the first sutures—a hypodermic of ergotole should be given before beginning the operation, and one of ergotole and pituitrin on the delivery of the child. Retraction of the uterus is ensured by manipulating it, if necessary, through a hot towel, or by faradism. When there has been much blood lost, a quart or two of warm sterilized 0.9 per cent. salt solution may be left in the peritoneum. The parietal peritoneum is closed with a plain running No. 0 catgut suture. Interrupted silkworm-gut sutures are then passed at intervals of about ¾ inch: through all but the peritoneum, from within outward. The fascia is brought together with interrupted No. 2 plain catgut sutures, or with a continuous suture. The silkworm-gut sutures are now tied. The abdomen is cleansed, and the wound covered with a dressing of several thicknesses of dry sterile cheesecloth; over this is placed a thick compress of sterile absorbent cotton. The dressings are secured with strips of zinc oxide adhesive plaster, and held in place by a Scultetus binder."—(Polak's *Obstetrics.*)

9. Face presentation.—*Diagnosis:* Vaginal examination will show a high position of the presenting part, and also a mouth or nose, which should not be mistaken for a breech. In L. M. A. case the chin is directed anteriorly and to the left acetabulum; no fontanelles can be detected. Abdominal palpation may reveal the deep groove between the child's occiput and back. *Mechanism:* The successive steps are: "Extension—The head presents at the superior strait imperfectly extended, so that every case of face persentation may be said to begin as a brow presentation. There is also at first imperfect engagement of the presenting part, on account of the large diameters presented at the superior strait. Under the influence of the expulsive action of the uterus and the resistance of the pelvic walls, the brow, caught upon the pelvic brim, is held stationary, while the chin descends lower and lower by an extreme extension of the head. Molding, or an accommodation of the shape of the presenting part to the shape of pelvis, occurs to a moderate degree or not at all, because the face is a loose fit in the normal pelvis. The molding is confined to the back of the skull. Lateral inclination is a constant feature, so that one cheek is a little deeper in the pelvic canal than the other one. Descent of the presenting part follows the dilatation of the cervical canal, the descent of the chin being accomplished almost solely by the extension of the head, and not by a descent of the head as a whole. Anterior rotation of the chin occurs as soon as it encounters the resistance of the pelvic floor. Anterior rotation is followed by the engagement of the chin under the symphysis pubis. Then follows the delivery of the head by flexion and propulsion, the mouth, nose, eyes, and forehead sweeping over the perineum and appearing successively at the posterior commissure. Restitution and external rotation follow the escape of the head from the same causes that impose those movements upon the head in a vertex presentation. The delivery of the body takes place as in a vertex presentation."—(Hirst's *Obstetrics.*)

Management: If the chin is presenting anteriorly, expectant treatment may suffice; but care must be taken to observe that the chin does not rotate backward. Spontaneous version may occur, and the presentation become a vertex one. Failing this, or as a means of favoring this, the postural treatment, such as Walcher's position, has been recommended. If, in spite of this, engagement has not occurred, cephalic version is indicated, care being taken not to rupture the membranes. If this is not successful podalic version should be tried. If, after all these manipulations, the child is still alive and the head is engaged, sym-

physeotomy is indicated; if the child is dead, craniotomy should be performed.

10. "*In mentoposterior positions* endeavor to secure anterior rotation of the chin when it fails to take place spontaneously. The several methods of attempting this are: 1. Press the forehead backward and upward during a pain, so as to make extension more complete, and thus cause the chin to dip lower down and touch the anterior inclined plane upon which it may glide forward. 2. Put a finger in the mouth or on the outside of the lower jaw, and draw the chin forward during a pain. 3. Apply the straight forceps and twist the chin to the pubes. 4. Apply the vectis, or one blade of the forceps, under the most posterior cheek, and over the anterior inclined plane, thus, as it were, thickening the latter, so as to make it reach the malar bone and constitute a *point d'appui* which the chin can touch and so glide forward. Should these attempts to secure anterior rotation fail, an effort may be made with the hand, vectis, or fillet, to bring down the occiput and convert the face into a head presentation. In order to succeed in this maneuver the membranes should be unbroken, the os uteri dilated, the face not so deeply engaged that it cannot be lifted to or above the pelvic brim, and an anesthetic administered. Again, failing in this way to produce anterior rotation, the head, if it be not too deeply engaged in the pelvis, and have not passed through the os uteri, may be pushed back, and the child be delivered by podalic version. Should none of these methods be practicable and the head become impacted in the pelvis with the chin toward the sacrum, the only resort is craniotomy. Attempts have been made in these cases to deliver by forceps after lateral incision of the perineum, but they can only succeed when either the child is small or the pelvis over-large. Usually the child's life has been so far imperiled by delay and its consequences that craniotomy may be done without compunction. Possibly symphyseotomy may prove useful in these cases in future. In all cases of face presentation special care is necessary to avoid rupture of the perineum."—(King's *Manual of Obstetrics.*)

11. "*The obstetric forceps* is an instrument devised for grasping the fetal head in difficult labor and by traction aiding its exit. There are two varieties—namely, the simple, including the short and the long, and the axis-traction forceps. A *short* forceps is one in which the blades of the instrument are attached directly to the handles without the intervention of a shank; it possesses the cranial or cephalic curve only—that is, the outward bulging of the blades by which its accurate adaptation to the fetal head may be accomplished; this curve should be the arc of a circle, the radius of which is about 4½ inches. The *long* forceps is one in which a shank is placed between the handles and the blades for the purpose of adding length to the instrument. It has, in addition to the cephalic the pelvic curve, or upward turning of the blade, corresponding to the curve of the parturient canal. By an *axis-traction* forceps is meant a variety of long obstetric forceps in which, by an appliance or supplementary handle attached to the under surface of the blades, the traction-force is exerted in the line of the axis of the parturient canal, and, therefore, rendered more effective, while at the same time it is reduced to a minimum. Traction is effected entirely by the supplementary and not by the primary handles."—(Dorland's *Obstetrics.*)

Indications for the use of forceps are: "1. *Forces at fault:* Inertia uteri in the presence of conditions likely to jeopardize the interests of mother or child. (*a*) Impending exhaustion; (*b*) arrest of head, from feeble pains. 2. *Passages at fault:* Moderate narrowing 3¼ to 3¾ inches, true conjugate; moderate obstruction in the soft parts. 2. *Passenger at fault:* A. Dystocia due to (*a*) occipitoposterior, (*b*) mentoanterior face, (*c*) breech arrested in cavity. B. Evidence of fetal exhaustion (pulse above 160 or below 100 per minute).

Accidental complications: Hemorrhage; prolapsus funis; eclampsia. All acute or chronic diseases or complications in which immediate delivery is required in the interest of mother and child, or both." (From Jewett's *Practice of Obstetrics.*)

Manner of using forceps: "They should not be used when the os is undilated, when the head is not engaged, except in placenta prævia, when the membranes are unruptured, when the disproportion between the child's head and the parturient canal is too great, or in impossible positions and presentations. Before applying the instruments they should be sterilized, preferably by boiling; and the patient anesthetized and placed in the lithotomy position. Two fingers of the right hand are introduced into the vagina; the left blade of the forceps is then held almost perpendicularly by the left hand, with the tip of the blade opposite the vulva; the tip is introduced into the vagina, and passed along the floor toward the sacrum. The blade is rotated outward in its long axis in order to escape the promontory of the sacrum. The right blade is introduced in a similar manner. To facilitate locking, one of the blades must be rotated forward. If the head occupies the right oblique diameter, as in L. O. A. and R. O. P. positions, the right blade must be rotated; if it occupies the left oblique diameter, the left blade must be rotated. Traction is made in the direction of the pelvic axis until the perineum is well distended. The perineum is then protected by one hand, while the face is swept over it by an upward movement of the forceps. In posterior positions it is necessary to remove the instruments after the head is drawn down to the pelvic floor; after anterior rotation is secured they may be reapplied. If the occiput rotates into the hollow of the sacrum the hands should be depressed as the face is swept out under the symphysis pubis."—(*Pocket Cyclopedia.*)

12. The case is one of Sepsis.

THE RÔLE OF THE *X*-RAYS IN THE DIAGNOSIS OF URETERAL CALCULUS.*

BY WILLY MEYER, M.D.,

NEW YORK,

ATTENDING SURGEON TO THE GERMAN AND POST-GRADUATE HOSPITALS.

To discuss the rôle of the *x*-ray in the diagnosis of ureteral calculus before an audience like this may seem strange at first glance. We all know its great value and rejoice in the light it has thrown on a subject which up to twenty years ago could often be recognized with difficulty only. We all are happy and proud to know that almost every hospital of standing in our States has a skilled and thoroughly trained radiographist on its staff, a man equal to the tasks before him, capable and reliable in the interpretation of the usually so interesting negatives.

Clinicians, therefore, have been quick to give radiography its proper place in the series of examinations necessary to enable them to arrive at a distinct and refined diagnosis; for if anywhere, then in the chapter of ureteral (and renal) calculus, is it necessary to "refine" the diagnosis as much as possible, before we have a right to resort to surgical interference. Only thus shall we be able to do full justice to our patients and avoid grave mistakes and sore disappointments.

Many surgeons have, therefore, gradually come to

Fig. 1.—Case I. Stone in left ureter (high).

advise the taking of a radiograph as *the first* step in the series of special examinations required, following the usual preliminaries of clinical and laboratory tests, in all cases with symptoms pointing to stone in the ureter (or kidney). I say advisedly, "or kidney," because the subjective symptoms of ureteral and renal stone are usually almost identical.

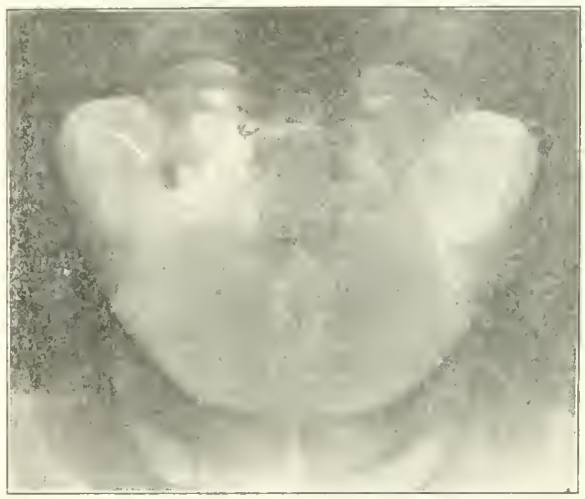

Fig. 2.—Case I. Recurrent stone in left ureter.

That this radiograph should be a stereoscopic one whenever conditions permit, cannot be too strongly emphasized.

Of course, the reverse arrangement of sequence, *i.e.* the *x*-ray following the special examinations, also has its advocates. However, I for my part, believe it wiser in this class of cases to have the clinician corroborate the findings of the *x*-rays than to have the *x*-rays corroborate the findings of the clinician. Generally speaking I believe that the only correct way, in every case, be it fracture or dislocation, cranial, thoracic, abdominal, or urinary disease, still is, to make *first* a clinical examination and diagnosis, same as we did twenty-five years ago, when we were not in possession of the wonderful aids furnished to-day by the laboratory, direct visual examination and radiography. I have long since come to the conclusion that also at the present time it is best in the given case to have the modern methods of more refined investigations bring out their respective proofs in corroboration or refutation of the clinical diagnosis previously reached. But in the chapter of suspected ureteral or renal calculus—and here *only* for the sake of greater convenience and comfort to the patient—I am willing to reverse matters with regard to the *x*-rays. I think we can thereby often save the patient the repetition of cystoscopy and ureteral catheterization.

To rely on the result of the *x*-ray examination alone is certainly wrong, and, I am sure, there are few surgeons to-day who would operate for ureteral (or renal) calculus, simply on basis of the history of the case, the result of the urinary analysis (blood

*Read before the Section on Genito-Urinary Surgery of the New York Academy of Medicine, October 20, 1915.

or red blood corpuscles in particular, right after a renal colic) and a careful study of the *x*-ray plates. Most surgeons would hesitate to do this, and rightly so, for we know that radiography has its limitations and fallacies, same as every other branch of

Fig. 3.—Case II. Two stones in right ureter.

medical science. We know, too, how much depends on the experience, ability and knowledge of the *x*-ray specialist in obtaining the correct interpretation of the shadows thrown on the plate.

Of course, there may be cases in which the indication for immediate operation is dictated by the urgency of the clinical symptoms in which the taking of a radiograph with prompt development of the plate is all that can be done for the patient. However, they are the exception.

Of limitations I know only one, namely, the inability of the rays, up to the present time at least, to demonstrate a pure uric acid stone, or one made up of phosphatic salts only. But these concretions are rare. Most ureteral calculi are composed of several salts and mixed with calcium, so that they throw a shadow.

As regards the fallacies to which a number of causes may lead, no one recognizes and appreciates them more readily and willingly than the radiographist himself. In general we rarely meet a class of colleagues who are, as a rule, more careful and reticent in rendering a definite conclusion on basis of their examinations. The few who boast that they know it all, who are ever ready for an immediate "definite" diagnosis on basis of their interpretation of the radiograph, without even having examined the patient or studied the laboratory—and other reports, these men will come to grief sooner or later and be forced to step down from the high horse they are riding.

Braasch enumerates these principal causes for the occurrence of fallacies: (1) Insufficient preparation of the patient, poor condition of tube or plate, and bad development of the plate; (2) the shadow of the pelvic bones obscures that of the overlying stone; (3) a very small stone, if arrested, may cause stricture and periodic urinary obstruction, and its shadow is overlooked.

To show the necessity of corroborating the diagnosis (either way) by *all* the means at our disposal before operating, in cases of impacted ureteral (or renal) calculus, and to briefly mention the efforts that have been made and the methods that have been devised to gradually improve the *x*-ray diagnosis in this chapter of surgery, is the object of these remarks. They will show at the same time how much we *owe* to the *x*-ray in demonstrating a

Fig. 4.—Case II. Two stones in right ureter.

suspected trouble clearly and graphically on the plate.

I am, of course, well aware that a great deal has been written on this subject. I did not have the time to study the voluminous literature. I will only mention the excellent articles that have just come out within the last few days, namely, "Errors in Diagnosis of Urinary and Ureteral Calculus," by Hugh Cabot of Boston, in *Surgery, Gynecology and Obstetrics*, October issue, and "Stones in the Ureter," by W. F. Braasch and A. R. Moore, in the *Journal of the American Medical Association*, Oct. 9, 1915. My remarks, therefore, cover only personal impressions, and while they may not contain

Fig. 5.—Case II. Both kidneys after nephrotomy. No stones over left twelfth rib visible.

anything particularly new, they may perhaps furnish a number of points worthy of discussion.

In order to bring out a few of the points I desire to make, permit me to give you, as briefly as possible, the history of three cases, selected from a series

of twenty or more of ureteral calculus that have come under my care within the last thirteen years. I say "or more," because I am not certain that every ward case has been included in the above number. In almost every instance the *x*-rays had shown the

Fig. 6.—Case II. Stone in left ureter, found March 5, 1914.

presence of the stone. In the majority ureteral catheterization with a wax-tipped stilette, either before or after the radiograph, made sure of the presence of the concretion within the ureteral canal. In some an additional radiograph was taken, with the *x*-ray stilette's tip being in contact with the stone. The cystoscopic and ureteral work was usually carried out by myself. Originally Kelly's method of catheterization was used, in order to obtain the scratch on the wax, in the female, at least. Later the ureter cystoscope of the Nitze type was employed in both sexes, with Burton Harris's clever way of introducing the wax-tipped catheter.* All the cases were operated upon by me personally, and all recovered from the operation. There has been no mortality.

I trust that I may mention at this juncture that I prefer the oblique transmuscular hockey-stick in-

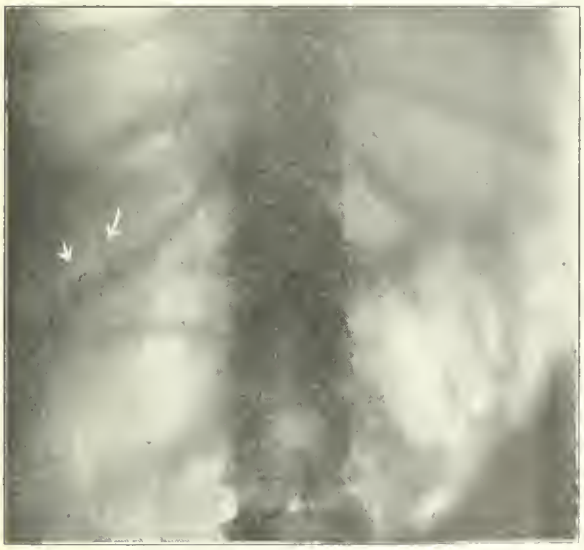

Fig. 7.—Case II. Two stones in left kidney

cision for uretero-lithotomy; that I always open the ureter right over the stone, doubly ligating and dividing, if necessary, in the female the uterine artery, which crosses the ureter transversely low down in the pelvis, and that I close the wound by interrupted chromicized gut sutures, trying not to include the mucosa. Layer suture of the abdominal wound with the insertion of a short cigarette drain, the lower end of which runs nearly, but not quite, down to the sutured ureteral cut, completes the operation. During the first twenty-four to thirty-six hours after the operation Sym's posture is maintained.

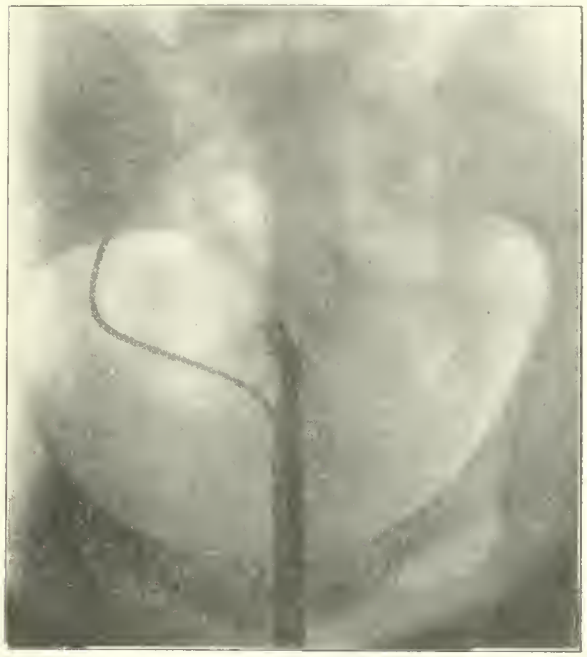

Fig. 8.—Case II. Wax-tipped *x*-ray stilette verifies presence of stone.

Case I.—Man, 30 years of age; stone in pelvic portion of left ureter, located by the *x*-rays and ureteral catheterization. No shadow in kidneys. Operation at German Hospital in June, 1910. Stone removed. Rapid convalescence. Three years later onset of identical symptoms on same side, with hematuria. Recurrent stone trouble suspected. Immediate roentgenogram shows an irregular concretion in the upper portion of the left ureter (Fig. 1); nothing in the pelvis. Prompt operation urged, but advice not heeded. Four weeks later the radiograph locates the calculus near the bladder, where it had been arrested in its descent (Fig. 2). Cystoscopy, with indigo-carmine injection, establishes the fact that the canal is only partially blocked. Now trial of non-operative methods proposed. Glycerin injections into the ureter at three different times fail to dislodge the stone. Then dilatation of the ureter up to the obstruction and application of the d'Arsonval current with Buerger's operating cystoscope at two sittings. Spontaneous passage of the concrement four months later. So far, complete cure.

To what extent the direct intraureteral treatment was responsible for the happy termination in this case I do not venture to say.

Comment.—This case has been reported in order to emphasize the invaluable assistance of the *x*-rays in promptly establishing the diagnosis: descent of a second renal calculus, the kidney having been found free from further concretions at the time of the first attack—on the whole a rather rare occurrence.

*The diagnosis of ureteral calculus by means of the wax-tipped whalebone filiform bougie used with the Nitze cystoscope. Surg. Gyn. & Obst., Vol. 15, 1912, p. 727.

The case represents an exception, clinically, because I refrained from the usual routine. But it would have been folly here to insist on further corroboration of the presence of the stone. In fact, I urged *immediate* operation, since a further quick descent

Fig. 9.—Case II. Shadows over twelfth rib: *x*-ray taken on day before operation.

of the stone was to be expected, most likely with another arrest in the region of the former operative field. From a surgical point of view, a transperitoneal operation would then have been preferable to the usual retroperitoneal advance, with its greater risk for the patient.

Case II.—Female, 45 years of age, herself a physician, wife of a colleague. First attack of severe renal colic on September 23, 1913; lighter attacks in the course of the following days. A radiograph taken on the seventh day of the disease shows the presence of two stones, one the size of a cherry pit, in the middle of the ureter (Fig. 3), the other, somewhat smaller, about two inches above the bladder. Ten days later a second *x*-ray picture was taken by the same roentgenologist at his office with the same apparatus. Report: "No stone present in the ureter; has evidently been passed." Pains in the renal and ureteral region, however, continue, and on October 26, somewhat more than a month after the onset of the trouble, fever sets in. On the following day rise of temperature to 106°. Then first seen by me. All symptoms could, of course, have been nicely explained on basis of a ureteral calculus. However, in view of the negative second radiograph—taken by a reliable and thoroughly trained man—the diagnosis was difficult. Temporizing under closest observation and subsequent cystoscopy with ureteral catheterization were advised, inasmuch as improvement of the clinical symptoms in such cases with the ureter not blocked by a concretion is not infrequently observed. Brief improvement *did* follow. However, on October 29, or forty-eight hours after I had first seen the patient, chills set in and continued to recur at short intervals. I did not learn of this condition until two days later, and then advised immediate transfer of the patient to the German Hospital. There the ureter catheter obtained clear urine from the left kidney, while on the right side the catheter was arrested 5 cm. above the bladder (Dr. Rehling). There was some tenderness over the right kidney posteriorly. Otherwise palpation negative. High leucocytosis. Of course, operation was urgently indicated, despite the negative *x*-ray findings. It certainly did not seem wise to await the result of

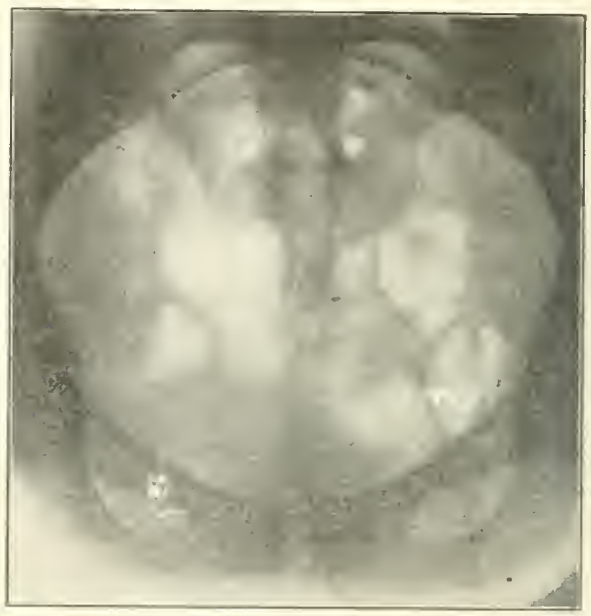

Fig. 10.—Case III. Stone in right ureter.

another radiograph. So nephrotomy was done by means of the longitudinal incision, with resection of the twelfth rib. Kidney large, brought forward: no edema of perirenal fat; no change of parenchyma macroscopically, but pelvis edematous, distended. Turbid urine obtained by aspiration. Bacteriological examination later on shows the presence of the *Bacillus coli communis*. The pelvis is incised and about two ounces of purulent urine evacuated. Sounds introduced into ureter downward give exit to pure pus, and find an obstruction and distinct grating 7 to 8 inches (18 cm.) downward. Drainage

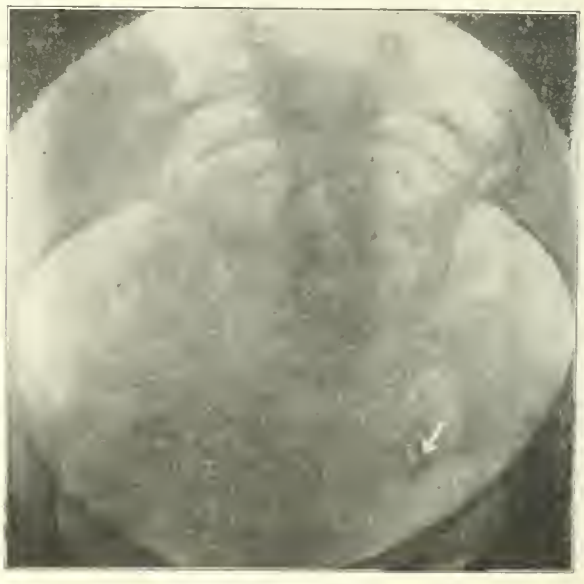

Fig. 11.—Case III. Stereo report: presence of stone in right ureter doubtful.

of ureter and pelvis; tamponade of wound, which is left wide open, not sutured. Quick improvement of all symptoms and gradual recovery, while kidney drains copiously through posterior wound. On November 21, or three weeks after the operation,

the ureter catheter again finds the obstruction 5 cm. above the right ureteral mouth; evidently a stone. Analysis of the urine collected from the left kidney now shows a pyelonephritis also on the left side, and the *x*-rays demonstrate again the two shadows in

Fig. 12.—Case III. Wax-tipped catheter proves no stone in ureter.

the region of the right ureter, one lower down and one further up, evidently calculi (Fig. 4), both kidneys being free of stones, Fig. 5. November 24, three and one-half weeks after the first operation, right ureterolithotomy. Both stones found and removed; ureter sutured in both places. Careful restoration of abdominal wall by layer sutures. Primary union. Two days later the posterior wound

Fig. 13.—Two stones in left ureter. (?)

is perfectly dry. The nephrotomy wound heals solidly within a short time. Patient in fine shape at time of discharge from hospital, December 16, 1913, three weeks after the second operation. Two and a half months later, on February 28, 1914, sudden acute abdominal pain with vomiting; repeated chills and fever up to 106°. On the following day tenderness localized in left lumbar region; urine turbid. Then seen by me. Immediate readmission to the hospital. *X*-rays show shadow in region of left

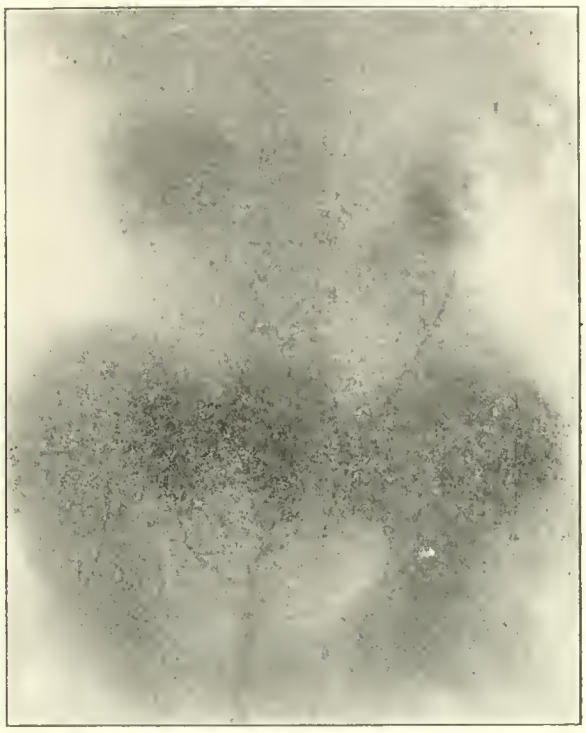

Fig. 14.—*X*-ray stilette in place.

ureter (Fig. 6) and two in left kidney (Fig. 7). Catheterization with wax-tipped stilette corroborates details of *x*-ray findings (Fig. 8): resistance 4½ inches (12 cm.) above bladder. Immediate ureterotomy on left side, following the principle I have laid down for myself, that it is best for the patient to first re-establish proper drainage of the kidney by the removal of an ureteral obstruction and then attack the kidney at a second sitting, about two or three weeks later. The stone is encountered somewhat below a line uniting the anterior superior spines. Ureter incised and stone lifted out. Careful sounding in both directions proves canal free. Suture of ureter; cigarette drain; careful layer suture. Prompt disappearance of all threatening symptoms. Primary healing of wound; rapid recuperation.

In order to corroborate the *x*-ray findings with reference to the left kidney, another picture is taken soon after and again on the day preceding the one set for nephrotomy. Both show the two shadows as in Fig. 7. Through a misunderstanding the latter covers the region of the left upper ureter, not that of the kidney (Fig. 9). Still, the twelfth rib is just visible at the upper corner of the picture, and over it are the two shadows interpreted as renal calculi. With the husband's consent I abstained from pyelography, but went ahead with the exploration on basis of the former findings. For I considered it imperative, after all the exciting experience we had had with this ever-cheerful and non-complaining patient, to guard against another complication, namely, passage of one of the suspected renal calculi into the ureter which had just been operated upon. The kidney is found large, but normal; a well-developed pelvis is not present. The overhanging parenchyma appears directly attached to the upper

portion of the ureter, which latter starts immediately from the organ. A transversely running artery of some size, which crosses the renal vessels, is doubly ligated and divided. While putting the kidney on the stretch in the attempt to unfold the upper end of the ureter as much as possible for more definite examination, the latter tears lengthwise, close to the kidney substance. This wound is lengthened and used for careful sounding. A small amount of gravel is evacuated, but no stone or calcareous deposit is found and no renal pelvis. The probe runs toward the upper pole of the kidney, always in the same direction, while its tip, bent to a curve, fails to proceed in various directions, as we are used to observe when probing the calices. Downward the ureter is patent and permeable for flexible bougies and a voluminous current of sterile water. Needling has a negative result. Further search for the suspected stones, as shown by the shadows in the *x*-ray picture, would have necessitated a section cut of the kidney, an addition which I did not urge, and the husband refused. Partial closure of the ureteral tear and layer suture of wound, with drainage. The wound healed kindly while the urine cleared up. The patient is discharged on April 14, three weeks after the fourth and last operation.

To-day, eighteen months later, the patient is in perfect health.

Comment.—What does this case teach? That the surgeon must not rely absolutely on the *x*-ray findings, even though the work have been done over again by the same roentgenologist and with the same machine. As stated above, the diagnosis in this case would have been perfectly clear and the clinical symptoms fully explained, had not the radiographist, in whose ability and knowledge of details I place implicit confidence, reported "ureteral stones evidently passed." Under such circumstances temporizing was indicated in order to await a more favorable time for ureteral catheterization. However, as symptoms grew worse, drainage of the respective kidney pelvis became imperative, and nephrotomy was done. Why the rays failed to show the stone at the second examination I do not know. The occurrence simply shows one of the uncertainties of *x*-ray work in ureteral disease. Perhaps a third exposure by the same colleague would have again shown the stones quite clearly.

Later on the *x*-rays in the hands of another radiographist, whose excellent work and good judgment I have learned to value most highly in the course of many years, again played us a trick when we tried to find the indication for an attack on the right kidney. The patient had wonderfully recuperated when this last operation was undertaken. Only the conviction I had that a stone *would be found* in the kidney, and the importance of avoiding the possibility of an entrance of these stones into the ureter prompted me to do operation No. 4. Why those shadows were not shown on the first photograph (Fig. 5) taken by this specialist, and why they were later on present on the plate (Figs. 7 and 9), and no cause found, I again do not know. The bits of gravel encountered certainly could not have been responsible for them. The section cut of the organ might have demonstrated it. No *x*-ray has been taken since the patient was last discharged from the hospital.

I would like to mention still the case of a third patient, because it proves so beautifully what we have learned in the course of time about localizing shadows that at first glance seem to be in the ureter.

Case III.—While still busy putting the finishing touches to this paper, the following case came under my observation: Female, 45 years old, married twenty-five years, mother of five children. Pain and dragging sensations in right side of abdomen and urinary bladder for quite some time. Consulted many physicians. Of late ureteral calculus was suspected. Radiograph taken, not stereoscopically. An expert's interpretation reads: "Stone in right ureter near vesical outlet" (Fig. 10). Five weeks later above interpretation confirmed by another radiograph taken by the same specialist; picture again not stereoscopic. Then seen by me: Right movable kidney (pronounced), tenderness over appendix region. Patient demands immediate operation for the ureteral calculus. Sent to hospital. Urinary analysis negative, no red blood corpuscles. *X*-ray taken, by chance again not sterescopic. Report: "Stone in lower end of right ureter; a small shadow on opposite side, most likely phlebolith."

Now, I had two concurring opinions on the result of *x*-ray examinations by two experts. However, inasmuch as I was called upon to operate, I felt the necessity of a corroboration of the radiographists' conclusions. It certainly must be exceedingly disappointing to the surgeon to expose and open the ureter and then find the canal patent from the kidney down to the bladder, an experience which, fortunately, I had not had to date, and which I wished to guard against. I therefore did ureteral catheterization with the wax-tipped stilette. Two different sizes could be pushed up 20 cm. and more without finding an obstruction, and without bringing out the typical scratch on the wax. An immediate further *x*-ray exposure could not be done, as it was late in the afternoon, and the laboratory was closed. In order to locate the shadow, perhaps now higher up, a stereoscopic picture was taken soon after, which made the first radiographic diagnosis doubtful (Fig. 11). Report: "The plane of the shadows seems rather far forward for the normal location of the ureter. It is possible, of course, that we may be dealing with a tortuous ureter on the right side, which occasions this position." Another stereo with the *x*-ray catheter in the ureter proves definitely the absolute patency of the canal, and the shadow in question about two inches in front of it, evidently a phlebolith or concretion in an appendix epiploica (Fig. 12).

Operation done by me a few days ago proved that the movable right kidney and concomitant chronic appendicitis have been causing the trouble and evidently have been in part responsible for the highly neurotic condition of the patient.

If the time at my disposal permitted, and the scope of this paper were more widely drawn, I would cite a number of other illustrative cases. I would mention the details of the history of a man of 50 years, in whom I, and later Dr. Torek, who succeeded me in service at the German Hospital, did pyelolithotomy, ureterolithotomy and splitting of the kidney on the same side for a suppurating stone kidney in the course of seven months. At last the patient's general health greatly improved, though colicky attacks persisted off and on. A radiograph still showed two distinct shadows, apparently ureteral calculi, on the same side, besides many shadows on the right (Fig. 13). However, the *x*-ray catheter, through which collargol was injected into the kidney pelvis (Dr. Rehling), brought out the fact that the two shadows had no reference to the ureter, at least not to the one through which the catheter had

slipped up (Fig. 14). Personally I have had no chance to make further inquiries as to what the shadows represented, as the man has left the hospital. It is possible that they are in the course of a second ureter. His right kidney, which seems to be the seat of a hydronephrosis and to contain many calculi, as shown by pyelography, was never operated upon.

I would also speak of the great value of the negative result of *x*-ray examination and of the use of the wax-tipped catheter in a very interesting case of ureteral stricture in one of my patients in whom pyelolithotomy on the same side of the stricture followed extirpation of the opposite kidney for an old pyonephrotic stone trouble. Here every clinical symptom plainly pointed to the presence of a stone, which however was not found, though searched for here as well as abroad. Finally autopsy corroborated the presence of a typical stricture, the presence of which had been demonstrated during life with the wax-tipped catheter which had no scratch. I could cite a number of other cases, but this would take too much time.

If I may sum up what I have tried to bring out to-night I would say:

1. The *x*-rays represent a wonderful assistance to the surgeon in diagnosing the presence of ureteral stones (and stones in the urinary tract in general).

2. In view of the fact that the *x*-rays show us the cause of the disease visibly on the plate I think they should have first place in the train of examinations, following the general clinical one.

3. The *x*-ray examination should be stereoscopic, whenever possible, and include both sides of the urinary tract.

4. In order to do full justice to the patient and to avoid disappointment to surgeon and patient alike, cystoscopy with ureteral catheterization should follow the *x*-ray examination.

5. A scratch on the wax-tipped ureteral stilette or catheter furnishes additional reliable proof of the presence of a stone.

6. If the question of expense has to be considered ureteral examination with the wax-tipped *x*-ray stilette may be combined with the first radiograph. The stilette may then be shown on the radiograph plate in direct contact with the stone, besides showing the scratch on the wax after withdrawal. However, in general, it seems better first to locate the stone with the *x*-rays and use the wax-tipped *x*-ray stilette at a second sitting.

7. A negative *x*-ray result plus missing scratch on the waxtipped ureter stilette may be accepted as proof of the absence of a ureteral stone in the given case.

8. Ureterography or pyelography is indicated before operation in every case of ureteral (or renal) stone, in which the place of the shadow and clinical data leave still room for doubt, although the additional, above-mentioned examinations have been carried out.

9. The radiographist should receive brief clinical details when the patient is referred to him. It is unwise to have him approach the case without knowing the principal clinical findings. Such knowledge will enable him to interpret the shadows more intelligently.

The above mentioned additions in examination and the constantly increasing skill on the part of roentgenologists in interpretation may be expected practically to exclude a mistaken diagnosis and subsequent uncalled-for operation.

700 Madison Avenue

SURGERY OF GASTRIC AND DUODENAL ULCER IN RELATION TO THE INSURANCE RISK.*

By HOMER GAGE, M.D.,

Worcester, Mass.

Medical Director, State Mutual Life Insurance Co.

As surgery encroaches more and more upon the domain of internal medicine, and new operative procedures take the place of medical treatment in so many of the commoner pathological lesions, the medical director finds himself constantly face to face with new problems in medical selection and with very little data upon which he can base accurate or satisfactory decisions.

In many instances this is because the operative procedures are so new that no accurate opinion as to their effect on longevity is possible. Even after the necessity of surgical intervention has become apparent, and has been generally accepted, it takes a long time and much experimentation to develop a safe and satisfactory technique.

The operative mortality must be reduced to a minimum so that the operative risk shall be eliminated as nearly as is possible. The mechanical result must be so nearly perfect that no disturbance of function, no disability not the necessary result of the original lesion, can be attributed to the surgical interference, and the relief from the distress and disability occasioned by the condition for which the operation was undertaken, must be greater and more lasting than can be secured by any other method of treatment.

Take for example the removal of the Gasserian ganglion for tic douloureux—having reduced the mortality to a minimum, having eliminated any unpleasant sequelæ due to the operation, and being assured by experience of a much longer immunity from pain than can be obtained in any other way, the surgeon feels that his interference has been fully justified.

And so it is; but here we see the difference between his point of view and that of the medical director. The latter must have a longer and a clearer vision. Not content with the degree of safety or the amount of relief secured, he must know in the case of a tic douloureux to what extent the insurance risk is impaired by its presence, and just how far that impairment is affected, if at all, by the relief from suffering which is so satisfactory to the patient and to the surgeon.

He must know what to infer from the presence of the original lesion. A brilliant and perfectly satisfactory surgical result will have little weight with him if the underlying cause of the lesion is a degenerative tendency which is unaffected by the removal simply of its manifest and most distressing symptoms. I think that failure to recognize this difference in viewpoint is the cause of much misunderstanding in the study of end results.

Another factor that is important for us to remember is that many of these procedures whose influence upon longevity we are called upon to determine, are really of too recent introduction to make accurate conclusions possible.

When one considers that almost all of the modern practice of abdominal surgery has had its origin and development within the professional lives of those present, one realizes how far we are from the

*Read at the twenty-sixth annual meeting of the Association of Life Insurance Medical Directors of America, Oct. 14, 1915.

end results which are necessary to statistical accuracy.

This is particularly true of the subject to which I venture to ask your attention for a few moments to-day, viz., the Surgery of Gastric and Duodenal Ulcer in Its Relation to the Insurance Risk.

In an address on Surgery in Relation to Life Insurance by Dr. W. J. Mayo, delivered before the American Life Convention at French Lick Springs last year, he said: "That an estimation as to the curability of any gastrointestinal disease, based on data that was accumulated previous to five years ago, is practically worthless."

Although this seems to be an exaggeration, I think a little further consideration will enable us to see the justice of an opinion which is founded upon the experience of the largest clinic in gastric surgery in the world.

We must remember that the surgeon didn't turn plumber until Doyen demonstrated the practicability of stomach drainage in 1895; that our knowledge of the relation, frequency, and importance of gastric and duodenal ulcers based on accurate statistical information instead of on traditional opinion has all been gained since 1900 and is a complete reversal of the formerly accepted opinion, and that our old views of the nature, progress, and possible results of these lesions have undergone an equally radical change—made possible by the disclosures of a study of the living pathology in all its various stages instead of being dependent upon a study of the terminal stages alone, as provided by the post-mortem examination.

So rapid has been the progress of our knowledge of these lesions that it is very difficult, if not quite impossible, to bring the earlier and the later reports within the same classification. Mayo's limitation of accepted reports to five, now six years, will be seen therefore to be by no means unreasonable.

When I undertook the study of this subject for this meeting I had hoped to be able to present the results of surgical interference in these cases somewhat in terms similar to the tables of our Medico-Actuarial Investigation, but after a very wide search in the literature of the subject and much correspondence, I have been disappointed to find that there are as yet no available statistics capable of such an interpretation.

My own personal experience has been far too small to be of value, but there is reason for much encouragement and hope in the establishment of follow-up systems in almost all of the great clinics of this country, by means of which a mass of material will soon be available for the construction of accurate percentage tables.

Meanwhile, however, you and I are having brought to our desks for inspection with rapidly increasing frequency applications for insurance from men who have had gastroenterostomy performed for the relief of ulcer, who have been completely relieved of all symptoms, have gained substantially in weight and general appearance, and who in their own opinion, in the opinion of their medical and surgical attendants, and most important of all, in the opinion of the general agent, are good insurance risks.

What shall we do with them? We must pass upon them even if we cannot yet obtain the statistical information necessary to express the insurance risk in its relation to the American table.

Fortunately we are not without much valuable information on the natural history of gastric and duodenal ulcers under expectant treatment and on the results of surgical interference. In the first place, we have established the fact that these ulcers are much more common than we formerly supposed—that they occur in men oftener than in women in proportion of three to one—which is contrary to our previously accepted opinion, and that they are essentially chronic, with a tendency to recurring exacerbations of activity at irregular intervals for many years.

How persistent this tendency to recurrence is was well illustrated recently in one of my own cases—a man fifty years old had always had what he described as a poor stomach, had been told ten years ago that he had gastric ulcer, and was treated medically in a hospital for some weeks with such marked relief that he called himself cured.

In the face of this history he obtained insurance five years ago in one of the companies here represented, and within two months received a policy from one of the large New York companies after a home-office examination.

Two weeks later, while on the train between Springfield and Worcester, he was seized with sudden abdominal pain with partial collapse, was taken at once to the City Hospital, a diagnosis of perforated ulcer made, and operation performed four hours later.

Gastric contents were found throughout the right side of the abdomen, and he died of general peritonitis on the third day. There was an opening on the lesser curvature of the stomach near the pylorus large enough to admit a lead pencil.

I cite this case not in derogation of the medical treatment he had ten years ago, for that had given him ten years of active business life without conscious disability, nor in criticism of the action of the medical department which approved his application two weeks before his death, because we have all been much in the habit of considering that ten years, or even five years, of complete immunity from symptoms, are enough to throw some doubt on the correctness of the previous diagnosis and to establish a reasonable probability that the trouble, whatever it was, had been permanently relieved.

My object in citing it is to emphasize what I have just said about the liability of these lesions to become active again, no matter how long the period of quiescence.

Joslin and Greenough followed ninety-nine cases of gastric ulcer for a period of five years after their discharge from the Massachusetts General Hospital. None had been operated upon. At the time of discharge over 80 per cent. were classified as cured. At the end of five years 40 per cent. only were well, 40 per cent. had already had recurrence, 8 per cent. had died of gastric complications and 4 per cent. of other causes, and they make this interesting comment: "It certainly is startling to realize that every other patient with gastric ulcer is either to have a recurrence of symptoms or is never to be well again."

I am convinced from my own study and experience that if the eighty-seven cases still living at the end of five years could be followed for five more the percentage of those living and well would show the same marked diminution as was found at the end of the first five, and that the natural history of untreated or medically treated gastric ulcer is such that its presence in the history of an applicant makes the insurance risk definitely and permanently substandard.

Although we have no similar statistics in regard to duodenal ulcer, we have good reason for believing that the results would be more favorable. But until statistical evidence is available the analogous pathology and clinical history of gastric and duodenal ulcer should make us extremely cautious in our discrimination between them.

Nor is this all. The study of living pathology made possible by gastric surgery has revealed gastric ulcer as the forerunner, if not the cause, of a very large proportion of gastric cancers.

In the Mayo Clinic 71 per cent. of the gastric cancers presented evidence of a previous ulcer, and in Moynihan's Clinic the percentage was 72. The transitional stages of these changes from ulcer to cancer have been frequently observed and studied. Excision of the ulcer has often revealed to microscopic examination a beginning malignant degeneration that was unrecognizable from a gross inspection of the specimen, so that W. J. Mayo assures us that it is often impossible at the operating table to tell a cancer from an ulcer.

All this makes for caution when we come to study the relations of a history of gastric ulcer to medical selection. The added liability of malignant degeneration does not apply to duodenal ulcer, except when the ulcerated area has spread to the stomach side of the pylorus. Why this is we do not know, but there can be no doubt of the fact that cancer very rarely follows ulcer of the duodenum, while it is a not uncommon result of ulcer of the stomach.

I have dwelt upon this subject of the natural history of these lesions perhaps longer than I should and at the risk of trespassing upon a field that belongs more strictly to the physician than to the surgeon, but I have done it because I felt that the natural tendency and results of these lesions should be thoroughly appreciated before one could fairly judge of the extent to which they are influenced by surgical interference.

Now what has been accomplished surgically toward removing the insurance hazard in these cases? Experience has demonstrated that relief is to be found by diverting the current of the gastric contents from the region of the ulcer by means of a new and more dependent drainage opening, and a posterior short loop or no loop gastroenterostomy is the operation of choice for accomplishing this purpose.

Whether or no the ulcer-bearing area should be excised at the same time is still *usb judice* with the more radical opinion at present steadily gaining favor. Our problem is the effect of a posterior gastroenterostomy with or without excision upon the applicant's future health and expectancy of life and from an insurance point of view its consideration falls naturally under three heads.

First, the effect of a major operation; second, the possible unfavorable results which may fairly be attributed to the performance of this particular operation; and, third, the effect of the operation on the lesion for the relief of which it was undertaken.

In considering the effects of major surgical operations on insurance one's mind reverts at once to the important paper read before this association in 1904 by Dr. John Homans on "The Effect of Mutilations on Longevity." Its general applicability is, however, considerably impaired by a failure to discriminate between the effects of the pathological condition for which the operations were performed and the effects of the operations themselves, and one is hardly justified in drawing any more definite conclusions than that operations often fail to interrupt the natural course of disease and sometimes create new sources of disability and impairment.

In the report of the medico-actuarial investigation, recently published, is a table on the effects of major surgical operations which shows a mortality of 132 per cent. of the insurance table. The group is not a homogeneous one, comprises a great variety of procedures, and is made up of but 238 cases.

On the other hand, the table in the same report devoted to the effect of appendectomy shows a very favorable result, and yet surely this ought to be regarded like every laparotomy, as a major surgical procedure, frequently accompanied by the gravest constitutional disturbances, by severer shock and greater liability to adhesions and adhesive bands than is the ordinary gastroenterostomy. I think we have no reason yet for assuming that an operation *per se* adds anything to the insurance risk, provided the immediate recovery is satisfactory and complete.

There are, however, certain anatomical or mechanical complications which may follow as the direct result of operative interference and which may have an important bearing on the insurability of an applicant.

In the case of gastroenterostomy the applicant is of course expected to furnish evidence that the result of the operation is entirely satisfactory at the time of filing the application. This eliminates the cases in which the contents of the stomach pass out through the natural or the artificial opening, only to find their way back into the stomach through the other one, the so-called vicious circle—a most serious complication, which usually presents itself, if at all, during convalescence and is not met with after the modern short loop operation.

Another cause of failure manifested by a return of symptoms after an interval of relief is the occurrence of a jejunal ulcer in the neighborhood of the anastomosis. It appears ordinarily within a few months or a year after the operation, and, in the opinion of C. H. Mayo, is due to the use of nonabsorbable sutures.

It was never a common complication, and may perhaps be eliminated by the use of catgut instead of silk, but its influence cannot be wholly ignored in a consideration of the insurability of these cases as standard risks during at least the first year after operation. But after these dangers have been eliminated there is no reason apparent why the new drainage should not work as well as the old.

In the congenital pyloric stenosis of infants, where the problem is free from any pathological complications, the results seem to be uniformly successful. Scudder, who has had very large experience in these cases, in a personal communication, says that all of his patients who have survived the operation show a normal uncomplicated development, and one of them is now ten years old.

It would seem reasonable to infer, therefore, that those cases which are well at the end of one or perhaps two years after operation would thereafter present no impairment that could be directly attributable to the effect of the operation itself.

Lastly, we have to consider the effect of the operation upon the lesion for the relief of which it has been undertaken. Here is where we ought to have our table showing the mortality after five, ten, fifteen, and twenty years—and until these are forthcoming we cannot accurately estimate the degree of impairment in these cases.

Meanwhile we must try to obtain from the clinical reports of end results all the data that we can bearing upon the insurability of these cases as standard risks.

In 1905 Mumford tabulated the end results in 147 cases of gastroenterostomy performed for the relief of pyloric obstruction due to ulcer by different operators. These were the cases in which the immediate results were good, but in 25 or 17 per cent. of them the end result is described as "bad."

These were of course early cases done before the indications for operation and its technique had been standardized; but they are certainly not encouraging from an insurance point of view.

In 1912 Moynihan reported his results in 186 cases of duodenal ulcer operated on between 1900 and 1911. The operative mortality was 2 per cent., 6 per cent. were not heard from, 80 per cent. were cured, 2 per cent. died of other causes, and 10 per cent were more or less improved. In other words, 12 per cent. were, from an insurance standpoint, unsatisfactory, and this is the more significant because these were all duodenal ulcers which are admittedly more favorable than ulcers of the stomach.

This is illustrated by the figures published by Graham from the Mayo Clinic in 1913. Of 438 cases of duodenal ulcer, 88 per cent. are reported as cured or as having made satisfactory improvement, and of 162 cases of gastric ulcer 80 per cent. only were regarded as cured.

These operations were all done from 1905 to 1911, and at least two years had elapsed at the time of the report. There were then 12 per cent. of duodenal and 20 per cent. of gastric ulcers in which the clinical results were unsatisfactory, and the insurance risk therefore still more or less impaired.

The most recent figures are from the Roosevelt Hospital clinic in New York, and were reported by Peck at the American Medical Association meeting last June. Of the cases of duodenal ulcer the results in 88 per cent. of those heard from were good and in 12 per cent. poor, while of the cases of gastric ulcer he says: "Our results in this series are much less favorable than in the duodenal group, and the series is too short and many of the cases too recent to make our deductions of much value."

The striking thing about these statistics is, it seems to me, their uniformity. When three widely separated clinics of the highest repute agree that in practically 12 to 20 per cent. of the cases the end results are unsatisfactory there would seem to be little doubt as to what should be the attitude of a medical director who is trying to eliminate substandard risks.

It will be remembered that in studying the natural history of these chronic ulcers we found that the two most prominent characteristics were a tendency to repeated recurrence of the symptoms of indigestion and in the gastric ulcers a tendency to the development of cancer, and these two characteristics appear with equal prominence in the unsatisfactory results after operative interference.

It is impossible from our present data to say just how great is the danger of a subsequent cancer, but that it cannot be disregarded, at least in the early years after operation, is evidenced by the fact that Mayo Robson in 1904 reported that out of 112 cases of gastroenterostomy for simple ulcer four had died later of cancer, one at the end of one year, two at the end of two and one-half years, and one after three and one-half years, and that all had enjoyed good health between the operation and the development of the cancer symptoms. One of my own cases made a perfect recovery and for a year seemed to be in perfect health. Three months later he died of cancer of the stomach.

Peck says that "the well-known trend of gastric ulcers to undergo malignant degeneration, with the fact that a greater percentage fail to heal after simple gastroenterostomy has made me feel the desirability of excising such ulcers when it can be safely done." But of his two cases treated by excision without gastroenterostomy, one returned three years later with cachexia and probably cancer, and of his thirteen simple gastroenterostomies one developed cancer a year after the operation.

Gerster refers to the very good operative results, but calls attention to the number of clinical failures due to the development of cancer, and Lilienthal speaks of three cases in which carcinoma developed at the pylorus years after the performance of gastroenterostomy.

Rodman, who presented an exhaustive study of the subject to the American Surgical Association in 1914, concluded that "after carefully reviewing the statistics furnished me, I am impressed with three things—first, the operative mortality (which doesn't interest us) following gastroenterostomy has not been less than 5 per cent.; second, the end results are frequently disappointing to the surgeon and disastrous to the patient, and third, a number of perfectly satisfactory gastrojejunostomies from an operative point of view, the patients remaining well for a year or longer after operation, were followed by malignant disease or death."

He believes that the ulcer-bearing area should be excised, and, as I have already said, this opinion seems to be steadily gaining favor, especially insofar as it relates to gastric ulcers. Of course, no statistics are yet available to prove its superiority over the simple drainage operation, but the mere fact of its increasing popularity is of importance to us because it indicates a growing dissatisfaction with the present results.

In this brief and very imperfect review of the operative results in cases of gastric and duodenal ulcer it must be remembered that I have referred only to the opinions and results of men of the largest exeperience, familiar with the gross appearances of these lesions and possessed of every facility for accurate pathological diagnosis.

But the cases which are reported to the medical directors have not in many instances had the benefit of such expert attention or such careful study. At the hands of surgeons whose experience with these cases is small, whose opportunities for becoming familiar with their different phases are but few and far between, and whose clinics do not have the facilities for accurate pathological investigation, the results will certainly be inferior to those which we have been studying, and our decisions as to the general insurability of these cases must be based on average results, not upon the results of selected operators.

No one can appreciate more than I how unsatisfactory from an insurance point of view is such a study of this problem as I have presented. It would have been so much more convincing to have been able to say that of 500 cases operated on in 1905 and discharged well, the mortality in the first year was 140—gradually diminishing each year until at the end of the fifth it was only 100, and that after five years it was less than 100 per cent. of the tables—but unfortunately such statistics are not available.

In the meantime we cannot avoid the responsibility of a decision, and it must be made on the basis of such clinical studies as are now accessible, of which those which I have recited seem to me the most reliable and most illuminating.

From these it is, I think, a fair deduction that the surgical treatment of gastric and duodenal ulcer by gastroenterostomy, though a distinct improvement over the older methods, in spite of the unquestioned brilliancy of its results, has not entirely removed the tendency to recurrence of symptoms and dangers in both lesions, and in case the gastric ulcer has failed to eliminate the danger of subsequent cancer.

I hope that fuller end results tables may in the future enable us to minimize if not entirely to overlook all of these dangers, but on the basis of our present knowledge my own conclusions are that a history of gastric or duodenal ulcer in an applicant for insurance constitutes a permanent impairment of the risk, an impairment that is less but not lost after the performance of a gastroenterostomy, and that such applicants are not to be rated as average risks, insurable at standard rates.

SEVERELY IMPAIRED AUDITION IN CHILDHOOD.*

By LESTER MEAD HUBBY, M.D.,

NEW YORK.

SEVERE deafness occurring during the first four years of life, invariably results in mutism unless special educational methods are undertaken. Severe deafness occurring from the fourth to the eighth year of life, often results in loss of speech notwithstanding considerable didactic efforts. Severe deafness occurring after the seventh year seldom leads to mutism. However the child that can not hear conversational speech at a distance of two meters, requires special educational attention. Inability to hear and speak constitutes deafmutism.

With our present knowledge of the methods of teaching the deaf child, mutism should occur only in the mentally defective, *i.e.* the feeble minded, the imbecile, and the idiot. Most deaf children are mentally sound.

Severe deafness in childhood may be congenital or acquired. The majority of the cases are acquired. Heredity and the intermarriage of blood relations are the most frequent causes in the congenital form. Consanguineous marriages play an important part in the production of congenital deafness, but the tendency to deafness must be present in the family before it can be accentuated by intermarriage.

The acquired form of severe deafness in childhood in the majority of cases comes from involvement of the perceptive mechanism of the auditory apparatus. Love has found that one-third of the cases followed meningitis, one-third scarlatina and morbilli and the remaining one-third, typhoid, diphtheria, mumps, pertussis, syphilis, etc.

Pathology.—The anatomical causes of congenital deafness may be summed up to consist of malformations or lack of development of the various parts of the auditory apparatus and of that part of the brain concerned in audition,—and intra uterine diseases of the above parts, such as inflammation of the tympanum and labyrinth, fetal meningitis, hydrocephalus, etc.

*Read at a meeting of the Riverside Practitioners' Society, Oct. 26, 1915.

In the acquired, the pathological changes may be any capable of producing severe deafness or total loss of hearing of both ears. In the majority of the cases the damage takes place in the cochlear nerve system somewhere from Corti's organ to the bulbar centers.

Diagnosis.—In the history, heredity and consanguineous marriage of those whose families have a tendency to deafness should be noted. In the acquired the occurrence of any of the diseases that might produce deafness must be sought. Syphilitic affections occur in infancy and at the age of seven to eight years mainly.

The auditory apparatus including the Eustachian tube must be inspected and tested for the presence of defects. Each ear must be tested singly for the perception of sounds, tones, vowels, and speech,—using an effectual noise apparatus for negativing the other ear when necessary.

The limits of perception for tones of different pitch should be determined in the older child, as the ability to hear speech (according to Bezold) necessitates the audition of at least the range from b′ to g″ (480-768 d.v. per second).

If the visible part of the auditory apparatus is found normal and all diseases, traumata, and toxins that might affect the cochlear nerve system to the bulb have been excluded, and severe deafness of the type occurring in faulty function of the perspective mechanism of audition is present, then a further anatomical search must be made up to the cortical centers of hearing in the temporosphenoidal lobe of the brain. Thus Starr reports that pontine disease involving both lemniscus tracts has produced deafness in one-sixth of his cases.

Cortical lesions at the auditory centers on both sides of the brain may cause total deafness but this is extremely rare. Lesion in the auditory center on the left side in right-handed individuals, and on the right side in the left-handed, may produce the various types of psychical deafness, such as mind deafness, amusia, sensory aphasia, etc. Then the question of the presence of a more general defect of the entire brain must be sought preferably by a neurologist.

The feeble minded are those that are slow to learn to walk, lack the ability to concentrate long, are wanting in reasoning power, judgment, and self-control. Imbeciles can acquire simple ideas. Idiots are lacking in the power of acquiring ideas or concepts and cannot even be trained to keep clean.

Impaired development of speech may be caused by feeble mindedness associated with some deafness. In imbecility speech is developed but vocabulary is limited to the simplest phrases. In severe idiocy speech is lacking or limited to a stammering of articulated sounds. In this form there are marked changes in the speech centers.

The amount of deafness in deafmutes varies from complete up to the perception of words spoken near the ear. Over a fifth are totally deaf according to Schmaltz. Deafness is seldom complete on both sides. Tone perception islands are often found. Upper tone loss is less frequent than that of lower tones in the congenitally deaf, while the reverse is true in the acquired form. Some audition is more commonly present in the congenital than in the acquired type.

Kreidle has found the vestibular nerve affected in 56 per cent of deaf mutes. This explains the duck walk, which consists in a swaying gait with

the feet far apart, and also the inability to maintain the erect position without swaying (Romberg) or to stand on one foot, with the eyes closed, which is so frequently the case with the deaf-mute.

Prognosis.—This is more favorable in the congenital than in the acquired forms, as in the majority of the latter there is a total destruction of the cochlear nerve or its terminations in Corti's organ. A few spontaneous recoveries, more or less complete, of the congenitally deaf have been reported in the literature, but these have probably been either mistaken diagnoses or cases of psychical deafness. The latter of course are often curable with training.

Recovery is impossible where the cochlear nerve system has been destroyed as in meningitis, suppurative otitis interna, hydrocephalic pressure, etc.

Prophylaxis and Treatment.—Intermarriage of the congenitally deaf should be avoided. Physical defects of the nose and throat should be attended to at as early an age as possible, to avoid the dangers of middle and internal ear inflammations.

Discoverable defects in the auditory apparatus must be treated and overcome as much as possible, and the audition thus made as efficient as the crippled condition will permit. Among the poor and ignorant, children with severe deafness may be sent to institutions for the deaf without any effort having been made to improve the audition.

The majority of the severely deaf children are well endowed mentally. Mental defectives must be treated in a class by themselves, and further separated according to the amounts of intelligence present. Before attempting the amelioration of deafness an accurate determination of the amount of hearing in each ear must be made by an otologist.

Hearing exercises for developing latent audition have been tried with some success in selected cases. They should also give the idea of inflection and thus help to overcome the tendency to speak in a monotone.

The treatment of the ears with sonorous vibrations by means of an instrument such as the Zünd-Burguet electrophone will accomplish this more quickly than the unassisted voice.

C. Fernet advocates exercising the ear by listening to a clock gradually made more distant until inaudible. By listening at that point for awhile, gradually the sound will be heard again. By repeating this exercise he thinks the hearing can be improved. This would be applicable only in the most favorable cases.

There are three methods of educating the deaf-mute or the extremely deaf child—the manual method, the oral, and the combined manual and oral method. The manual method consists in instruction and in teaching the child to converse, wholly by means of signs with the hands and fingers. In the oral method speech and lip reading are taught. The combined method consists in the use of both methods.

The manual method unfortunately was first introduced into this country. It requires fewer teachers and less time than the oral method, but it places the pupils in a class apart and they are unable to work with those that have hearing. On the other hand, those taught by the oral method can converse and work with their fellows who have hearing. In 1908 more than half of the severely deaf children in the United States were taught by the oral method and it is hoped that in another generation the manual method will have disappeared in this country. The combined method has not proved a success. To learn to speak and read lips requires all the concentration and patience available and the short cuts of manual signs must be interdicted.

The mother of a deaf child, when there is some residual hearing, should develop the latter, by talking and singing into the child's ears, and begin the teaching of lip reading.

At the age of four years, a child that is strong and well developed should be sent to an institution for the deaf. The time of most rapid brain development is from 2 to 7 years, and that most favorable for language acquisition is from 2 to 12 years, therefore it is most important that the child be not neglected at this time. The deaf child of five starts behind the hearing child of two, according to John D. Wright. By the age of 15 or 16 in a special school, he has very nearly caught up to those who hear. Those losing audition up to 8 years of age, quickly lose articulate speech and should be placed under instruction as soon as they are in fair physical condition. It is very much better to send the child to a school than to have a single instructor at home.

The following methods are used to develop articulate speech. When there is some hearing, the sounds can be imitated after listening to them through acoustic tubes, etc. The movements of the lips, tongue, and larynx are studied visually, and with the finger tips feeling the muscular movements and the vibrations. The shapes of the moisture films, produced on a mirror or cold blackboard in saying the different vowels and consonants are studied and imitated, also the effect of the latter on a flame. Dr. Scripture has devised a revolving disc with alternate black and white squares, with a gas light attached to a speaking tube reflecting the vibrations of the flame produced by the sonorous waves upon this disc. By means of this apparatus the varying pitches of one's voice can be watched and altered in conversation or in singing. The inflections can also be improved by singing lessons. The position of the tongue when wrong is corrected by the instructor with the assistance of a spatula.

The majority of the schools for the deaf in this country are now using the oral method exclusively. There are 77 using the oral, 4 the manual, and 67 the combined method. New York City has five oral schools and one combined, and three of these are run by the city.

Deaf children, on account of their isolated condition, are liable to be of low physical development. Their carriage and gait are poor, and they are apt to shuffle their feet. Hence a varied physical culture under competent supervision is more essential than with the hearing child. Thus the various gymnasium exercises with and without apparatus, athletic games, dancing, drilling by word of command by means of lip reading, etc., should be prescribed according to the physical condition of the pupil. Swimming should be advocated with caution, as the deaf are prone to attacks of vertigo.

Deaf children are also successfully taught manual training and industrial work.

Fasting and Acidosis.—E. P. Joslin states that if a diabetic patient is fasted, acidosis disappears, and that this is in marked contrast to the behavior of normal persons for they present acidosis upon fasting.—*American Journal of Medical Sciences.*

THE CORRELATION BETWEEN OLFACTORY AND GENITAL FUNCTIONS IN THE HUMAN FEMALE.

By J. A. HAGEMANN, M.D.,

PITTSBURGH, PA.

THE existence of a correlation between certain intranasal tissues and the generative organs has long been a matter of universal medical knowledge. Perhaps the qualifying term "medical" is too limiting, for to many of the laity as well it is known that such an alliance exists. Althaus (Beitraege zur Physiolog. und Pathol. des Olfactorius) speaks of the mutual attraction of animals of opposite sexes for each other by olfactory perception of distinct odors at the period of rutting.

The symptomatology so far as it pertains to the male sex will intentionally be disregarded in this paper. In April, 1884, Dr. J. N. Mackenzie, in the *American Journal of the Medical Sciences*, published some physiological and clinical observations which he had made, and stated that "in certain women with normal olfactory organs regularly with menstruation a swelling of the erectile tissue of the nose occurs, that menstruation is at times replaced by epistaxis, and stimulation of the genital tracts is occasioned by affections of the nasal organs."

It remained, however, for Fliess, of Germany, to amend the imperfect knowledge which then prevailed regarding the dependency between certain functions of the nose and those of the female procreative organs. In 1887 he published a paper on "The Relation of the Nose and Female Genitalia," in which he affirmed that certain "genital spots" could be determined in the nasal mucous membrane, and that the anesthetization of these spots by the local application of cocaine would in many cases result in relief from the agonizing pain of dysmenorrhea, provided the same was not due to an obstruction of the cervix. The spots designated are the tubercle of the septum and the anterior part of the inferior turbinate. Later, Fliess had recourse to employment of the galvanocautery or trichloracetic acid in an attempt to lend permanence to the transitory palliation which cocaine bestowed. His postulate excited animated discussion throughout Europe. Kuttner criticised Fliess' theories unsparingly, pertinently asserting that it was unreasonable to admit that a controlling spot, located in the nose, should surpass and supercede any cerebral or spinal center. Many other European authorities also entered the lists for and against Fliess' assumptions.

His latest brochure consists essentially of a reiteration of his tenets, an arraignment of his detractors, and an augmentation of his theoretical intranasal genital centers by the addition of another center dominating the abdominal pains experienced by self-polluting girls. After stating that the primary changes in the nasal genital spots are frequently of an infectious nature, and admitting that these changes are not the sole solution of the distal manifestations (dysmenorrhea), he adds that "the anatomy of this neuralgic conversion is as unsolved as the nature of the structural change, for example, in neuralgia of the trigeminus or ischiatic nerve." In essaying to substantiate his postulate by producing evidence of anatomical relationship, Fliess says: "In the nose the erectile bodies are under control of the sphenopalatine ganglion, which receives sympathetic fibers from the carotid plexus through the petrosus profundus nerve. There would thus be an anatomical path to the sympathetic, which controls the sexual functions as well."

In the absence of an affiliation with a gynecological clinic, the writer has not had adequate opportunity afforded to verify or confute, to his own convincement, the conclusions of Fliess; but nasal phenomena analogous to, yet differing from those described by him, have been encountered by me a number of times. The specification of these phenomena and their interpretation is the *raison d'être* of this paper.

It may not be amiss to interpose here, by way of premise, a compend of some of the more relevant præcognita.

The olfactory sense indubitably exercised a paramount influence in the survival and development of the primeval zoological forms which were wafted to and fro by the waters of the "vasty deep" in the earliest faunal geneses. The low forms of animal life which had progressed beyond the amebic stage, and in which there had been evolved an incipient tactile sense, would in the prevailing course of events gradually develop a discriminating faculty which would, at an early period, subserve the selecting of nourishing, and later savory food. Coeval with this development there would be revealed the earliest traces of sexual evolvement, for sustentation and propagation in binary, rudimentary form, constituted exclusively the functions possessed by these primitive embodiments of animal life. One can readily idealize that in this elementary stage of evolution through which the primal forms of life were passing, there could be no great development of a selective faculty.

It is, however, conjectural that a more specific sense, if any, developing gradatim from the rudimental tactile perceptivity, would be in the nature of an olfactory faculty. In other words, as the incalculable successive generations of animalcules became more highly organized, a capacity to choose palatable food and perceive a conjugal mate must imperceptibly, but unintermittently have become established; so that, by slow degrees, the nascent organisms became both sensory and sensuous. If we pass over a diuturnity and study animals high in the scale of evolution we encounter the culminating degree of this development. To review, even cursorily, the interminable intermediate transitional forms would be a stupendous task. Let it suffice to say that this binate faculty, so common in primary forms, is retained by many that have progressed sufficiently to no longer require either or both capabilities in the struggle for existence. The males of a considerable number of mammals possess odoriferous secreting glands which in various species, are situated in different parts of the body. In certain ones the odor becomes more evident during the breeding season. It is confirmed that the females of these several species, during the rutting season, lustily exercise their olfactory endowment while experiencing a disposition to associate with the males. The consequent hyperemia of the olfactory area conformably produces tumescence and hypersecretion in this section of the nose. It seems idle to seek an anatomically linked bond, via the nervous system, between the olfactory and conjugal functions, for these developed contemporaneously, in multiform alliances among low as well as higher forms of life, according to the several requirements of the respective organisms.

If we contemplate that the perception of savory odors "makes the mouth water," that hearing a patriotic air may produce profuse lacrymation, that the witnessing of a touching scene may cause a "lump in the throat," all involuntary and presumably irrelevant sequences, we realize the futility of speculating upon an anatomical vinculum. It is more to the purpose for us to keep in mind that some brain centers apparently perform dual offices, or that two centers controlling different faculties act in unison in response to a stimulus from either of the distal areas whose functions they control. In the example under discussion, a sexual incitement may give rise to swelling of erectile bodies in the olfactory region; or, conversely, certain odors perceived by the olfactory nerves may set up hyperemia in the genital organs. Moreover, in some forms a concordant execution of both functions is probably habitual.

When pondering the foregoing data it does not seem extravagant to propound the paradoxical theory that the olfactory excitation which occurs in some young women may be regarded as one expression of atavism. These residual nerve-functions, remainders of once active and essential faculties possessed by our ancestors, are now latent and dormant, and have long, long ago ceased to be proficuous. However, eradication of a dispensable function is consummated only after interminable periods of time, and irregularly there occurs a vestigial resurgence of one or another feature of atavism.

If one keeps in mind the foregoing postulate while scanning the following summary, an apparent corroboration of the theory above advanced is marked. Where an unequivocal correlation between nasal and genital functions exists, the pain and tumescence are found chiefly near the anterior portion of the *middle* turbinate and the section of the septum diametrically opposite and above this point. The turgescence observed in the lower part of the nose is probably due to continuity of the connective tissue, by reason of which transcolation of the fluids takes place from above.

Reduction, by cocaine and adrenalin, of the turgescence over the inferior turbinates in two salient nasogenital cases did not notably alleviate the distressing pain and sensation of pressure which was complained of at the portion of the nose between the eyes, whereas application of the same solution to the olfactory field afforded prompt, but only transitory, relief.

Bilateral edema of upper and lower eyelids that had manifest genital dependency twice subsided within a few hours after application of cocaine and adrenalin solution to the olfactory field. In this instance there evidently was a dehiscence in the laminæ papyraceæ, permitting a "damming out" of the fluids which the limited space within the nose could not contain.

Surgical treatment by means of inferior turbinotomy or turbinectomy, will, in a disconcerting number of cases, fail to benefit the class under discussion, whereas removal of the anterior half of the middle turbinate, supplemented, if necessary, by a submucous resection of the septum, secures permanent deliverance from the recurrent attacks.

His clinical observations, differing in several respects from some published by other writers, and his deductions, arrived at from disparate premises, are the writer's plea in justification of this paper.

TORSION INJURIES OF THE MUSCLES OF THE ABDOMINAL WALL.

By GUSTAV F. BOEHME, JR., B.S., M.D.,

NEW YORK.

NEUROLOGIST TO THE WEST SIDE GERMAN DISPENSARY AND HOSPITAL; ASSISTANT PHYSICIAN, NEUROLOGICAL INSTITUTE, ETC.

IT is surprising, in looking over the literature of injuries to the abdominal wall how little material is at hand. Contusions, perforating, and penetrating wounds are discussed, but, as a rule, the ultimate subject discussed is not the injury to the abdominal wall per se, but the possible injuries to the viscera associated therewith. It is because of this fact, and because of certain injuries of this type, that I have seen, that I present this paper.

By torsion injuries to these muscles is meant any injuries to them or their muscular attachments, caused by the sudden rotation of the body on its vertebral axis laterally, or the sudden extension of the abdominal muscles by a movement in the vertical plane.

The cases (four in number) that I have seen were brought about by the sudden throwing of the weight with the twisting of the body laterally.

Case I.—L. S., a laborer in a tea-house attempted to lift and throw a tea-chest weighing some fifty pounds onto two other superimposed chests. He accomplished the act, but at its culmination he felt a snap in his left side, with a sudden pain, and then collapsed. On attempting to rise, he found that this was impossible because of a localized painful area in his left side. He was sent home and for some period of time was unable to resume his work.

Case II.—J. P., a laborer, after a blast picked up a heavy piece of rock and tried to throw it some distance. Instead of succeeding, the rock only flew a short distance, and he sank down with a sharp pain in his left side and was unable to resume his work.

Case III.—A ball player was throwing a ball from the out-field and used a force out of proportion to the muscular energy necessary to do so. He felt a sudden sharp pain in his right side and had to quit the game because the pain was so severe on every occasion when he again tried to throw the ball.

Case IV.—K. J., a professional acrobat, in practice, attempting to straighten his body from a knee-hold, suddenly felt something give way in his left side with a sharp pain and could not complete his act. The attempt at elevation, with its strain on the abdominal muscles, had been sufficient to cause an injury to them.

It will be noted that in all these instances the traumatism was occasioned by the sudden contraction of the muscles of the abdominal wall against a resistance. There was a sense of something giving way with a sharp pain, and these were found to be an inability to repeat the attempt. In some instances breathing, where of the abdominal type, was painful and markedly limited.

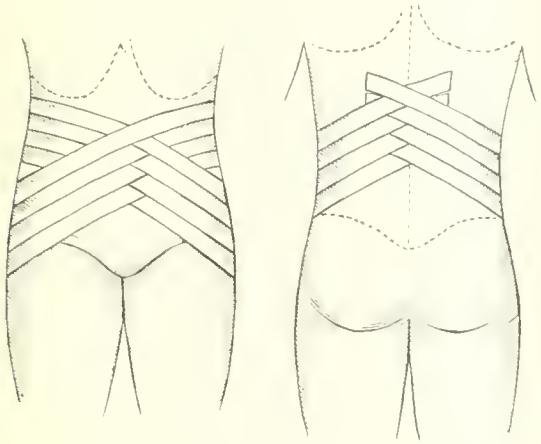
On examination a point of tenderness was made out, either in the rectus injured or in the oblique muscles (three cases). Sometimes a slight separation, as evidenced by a dimple-like depression on attempting to use the muscle, could be made out. Movements using these muscles were very much limited by pain at the site of the injury.

The pathology of the process is simple. Apparently with the intense muscular strain certain fibres in the recti or olique muscles are ruptured and the tear creates a painful area within the muscle bodies.

The treatment at first was something of a bugbear. Tight bandages were employed but gave only transitory relief, as did abdominal belts. Local applications in the form of counterirritants or lotions gave little or no relief.

Finally an adhesive plaster dressing was employed

which has proven eminently satisfactory. An adhesive band, 2 inches in width, was started just external to the anterior superior spine of the uninvolved side and carried in the general line of the external oblique on the involved side, around the body to the opposite side of the vertebral column. This was applied during complete expiration. From the opposite anterior superior spine a similar band was carried in the direction of the uninvolved external oblique, crossing the first band at the median line and ending on the opposite in the back. As



many bands were carried up the body as was necessary to immobilize the abdominal wall and to relieve the pain.

The relief was instantaneous, the patient was able to resume work of a general variety, although torsion movements were interdicted. As a rule, recovery ensued in about two weeks.

These torsion injuries occur more frequently than is generally supposed and their treatment, as outlined above, will be found materially simplified.

MENTAL DEFECTIVES; THEIR IMPORTANCE.

By H. VALENTINE WILDMAN, JR., A.B., M.D.

NEW YORK.

ASST. SURG. U. S. PUBLIC HEALTH SERVICE; FORMERLY ASST. PHYS. MANHATTAN STATE HOSPITAL; ATTENDING PHYS. CLEARING HOUSE FOR MENTAL DEFECTIVES.

Why of late years have those of the medical profession interested in mental disease been devoting a great deal of their attention to the mental defective of the higher grade? Why has the defective individual been attracting so much notice? Is he a type that fits with the large group of insane, on the one hand, or with the group of idiot on the other? Is he a new type—some outgrowth of conditions under which we live at present; some product of modern civilization? If he is neither idiot nor insane, why should so much interest be centered upon him? Why should so much time and money be spent devising methods to detect and control him? Why, if a foreigner, should he be denied admission to the country? In other words, what does the term "mental defective" convey? What is he? Wherein does he differ from other mental types? Why is he difficult to detect? Of what social or economic importance can he be that he should be the object of so much attention, country-wide in its extent?

The reason for centering of so much attention on these members of society is that it is now recognized that they are a menace to the race by breeding defective descendants who are most likely illegitimate as well, and that they are one source of great expense for this country, on the whole amounting, some say, to one hundred million dollars a year. These people, while dangerous, either actually or potentially when at large, may be made, under proper supervision, partially if not wholly, self-supporting, and can be thereby shielded from bad influences, which, in the nature of their trouble, they cannot resist, and from environments to which they would find it impossible to adapt themselves.

The mental defective is no new type, Cain, of biblical fame, being perhaps of the same stratum. He is, to repeat, no new type except in the sense that pellagra is a new disease in this country. He has always been with us, but the diagnosis has been made only in comparatively recent times, his lack of responsibility has only lately been appreciated. The separation and the realization of the importance of this type—this is new; not the type itself. The moron is ubiquitous and has been so, but his ability to harm has only recently been emphasized.

And now we come to the question of what is he?—this defective or moron as he is called? What are his characteristics? How can he be identified? Is simple inspection sufficient? Must more refined tests be applied? Does age enter into the question? In other words, what is he and how do we detect him?

Roughly speaking, it is extremely difficult, if not impossible, to make a diagnosis by inspection alone. The individual in question to the superficial view may make a fairly good impression and it is only by close attention to details of physical make-up that the suspicion may be aroused that the subject may be abnormal. These alterations in physical development are the so-called stigmata of degeneration to the importance of which attention has frequently been called especially by Lombroso. They consist essentially in abnormalities in the shape, size, or position of the head, ears, nose, and other features, or in a certain infantile cast of countenance. The suspicion having been aroused must be confirmed or refuted by a mental examination by a competent alienist.

In a given case this usually discloses an individual who is mentally years below his actual age, but not below the seventh year. A person with a mental age below seven is probably an imbecile and so defective that little or no difficulty is offered in his detection, and as he is not as likely to be allowed to run at large, he consequently does not present the menace the more highly developed defective does. The moron is deficient in some socially important trait which depends on some congenital difficulty or mental defect which shows itself in one of three main fields: in the domain of the will, or in the intellect, or in the development of the moral sense. He is particularly defective in the exercise of the powers of judgment and usually shows a marked inability to grasp the meaning or shades of difference of abstract nouns.

Another well developed characteristic of the higher grade defective is his ability to do a fair amount of work and get along well while under supervision or discipline, with utter failure when this is removed. This trait is particularly in evidence among the class of sailors or rather among

a certain percentage of the class of sailors. While under the discipline of the ship they perform their duties quite well, but when relieved from surveillance they are totally unable to care for themselves or their money. Although they may have worked hard for months and suffered more or less hardship yet as soon as disembarked they spend their savings with a lavishness and recklessness that has made the expression "like a drunken sailor" in reference to foolish extravagance, a by-word.

Therefore the reason for and the importance of the detection of this class of mentally abnormal individuals is quite self-evident. Left to themselves, they are an expense and a danger through either their moral lapses or their criminal delinquencies or both. If detected and segregated, they may be able to make their own living or they may not, but at least they are prevented from propagating a feeble-minded race.

108 West Ninety-fourth Street.

Medicolegal Notes.

Hypothetical Questions Based on Statements and Examination of Injured Party.—In an action for personal injuries where the plaintiff was seriously injured, but there were no broken bones, scars, abrasions, or other objective symptoms, it was held that the opinions of physicians as to the extent of the injuries, based on exclamations and other indications of pain, and the plaintiff's inability to handle himself, were properly admitted in evidence, under the general rule that a medical expert may base his opinions on the clinical history of a case, and, to make his testimony intelligible, may testify to observations made by him, and also as to what the patient said to him in describing his bodily condition, although an opinion based on mere self-serving declarations is inadmissible; the witness, in testifying to what he has heard, being confined to exclamations, shriekings, and other instinctive expressions. Hypothetical questions to medical witnesses, based, to some extent, upon matters within their knowledge through examination of the plaintiff, as well as upon matters entirely hypothetical, which the testimony of the plaintiff tended to establish, were held to be proper, no undisputed material facts being omitted, and all maters submitted therein being supported, to some extent, by testimony.—Biddle v. Riley, Arkansas Supreme Court, 176 S. W. 134.

Malpractice—Patient's Negligence.—In an action for malpractice in treating a broken leg it was held that if the condition of the plaintiff was the result of his own negligence in failing to take proper care of himself by attempting to treat the injury himself, the defendant physician was not liable.—Dunman vs. Raney, Arkansas Supreme Court, 176 S. W. 339.

Authentication of Physician's Books of Account.—In an action by a physician for services it is held that when books of account are offered in evidence to establish items of account, it is necessary to show by other evidence the correctness of the books. This may be done by testimony of those who have dealt and settled with the party from his books of account that he keeps fair and honest books of account, or, according to the later decisions, the correctness of the entries may be shown by the testimony of any one who is able of his own knowledge to testify to their correctness.—Colburn v. Parrett (Cal.), 150 Pac. 786.

In an action against executors for a physician's services to their testator, the right of the plaintiff was based exclusively upon the physician's book of visits. It was held that testimony of witnesses that they had settled their accounts with the plaintiff, not by his books, but by bills rendered to them, was not evidence of the accuracy of the books such as was necessary for their admission in evidence under the account book rule. And the plaintiff's own testimony that he kept correct books of account was insufficient to show their accuracy necessary for such admission.—Bellows v. Bender, N. Y. Appellate Division, 149 N. Y. Supp. 548.

Surgical Operation—Degree of Cure Required—Removal of Sponges.—Action was brought against a surgeon for negligently leaving gauze sponges in the body of a patient on whom he had operated, which resulted in her death. The defense was that the defendant was employed to remove the patient's ovaries; that he had the assistance of a trained nurse, who was not employed by him, but by the husband of the deceased, or some one on his behalf; that the operation was a difficult one; that it was necessary that he should keep his mind concentrated upon the surgical part of it; that he repeatedly admonished the nurse to keep accurate account of the sponges inserted into the cavity; that this was her duty, and that he impressed upon her the importance of seeing that they were all removed, and after the operation and before the cavity was closed, he asked the nurse if she had counted the sponges, and if they were all taken out, and she assured him she had counted them, and they had all been taken out; that he relied upon her statement, believed it to be true, and that all the sponges had been removed before the cavity was closed.

It was held that the defendant was entitled to an instruction on his theory of defense, and it was not error for the court to instruct the jury that, though they believed the defendant did leave the sponges in the body of the patient, and her death was the natural and proximate result thereof, yet if they also believed that, in the performance of the operation, he exercised ordinary care in keeping track of the sponges and seeing to it that they were all removed, before the incision was closed, he could not be held liable for negligence. The gist of such an action is not based upon the result of the operation, but upon negligence in its performance, and the rights of the parties must be tested by whether or not the defendant exercised that degree of care in performing the operation that is imposed upon him by law. Judgment for the defendant was affirmed.—Cassingham v. Berry, Oklahoma Supreme Court, 150 Pac. 139.

Proximate Cause of Death—Post-Operative Intestinal Cohesions.—Action was brought to recover damages on account of the wrongful, negligent, and careless leaving of a sponge in the abdomen of a patient, and on account of the defendant's negligence in permitting said sponge to remain in, creating an intestinal obstruction, resulting in a partial closing of a portion of the intestinal canal, and causing a partial paralysis and obstructions thereof, and by reason of such wrongful and negligent acts, and for no other reason, and as a direct result thereof, the patient died. It was held that it was incumbent on the plaintiff to prove said allegations by a preponderance of the evidence, and show that the presence of the sponge in the abdomen of the patient was the direct and proximate cause of the patient's death. It was also held that the evidence was sufficient to show that the adhesive condition of the patient's intestines caused her death, and that such adhesive condition was not caused by the presence of a sponge, and that the evidence was sufficient to support the verdict of the jury for the defendant.—Ruble v. Busby, Idaho Supreme Court, 149 Pac. 722.

Emergency Pauper Case—Liability of Relative.—In actions by a physician and a hospital for reasonable value of medical and hospital care, treatment and services rendered to a dependent relative in an emergency case, there was an urgent requirement for both physician's services and hospital care, imperative and admitting of no delay. It was held by the Minnesota Supreme Court that the plaintiffs could recover from a relative, upon whom rested the statutory duty to support such dependent relative, compensation for the reasonable value of such services, even though such services were rendered without the knowledge of the relative sought to be charged.—Tyron vs. Town of Moyer, Minnesota Supreme Court, 153 N. W. 307.

Expert Evidence as to "Probable" Effect of Injury.—In an action for personal injury causing a fracture of the skull and necessitating an operation which removed a part of the skull bone and some of the brain tissue, the doctors who attended the plaintiff testified in effect that there could never be a complete recovery from the condition described. They testified over the defendant's objection that the probable effect would be that the man would continue in a state of nervous and physical debility, more than likely to become epileptic and possibly insane or demented, that twenty out of 100 who sustain such injuries become subject to epilepsy, insanity, or some form of dementia. It was held that although the jury could allow compensation only for such future disability as was reasonably certain, the physicians' testimony was admissible, as they were not required to go any further in their statements than their candid opinions would warrant.—Manton vs. H. L. Stevens & Co., Iowa Supreme Court, 153 N. W. 87.

MEDICAL RECORD.

New York, December 25, 1915.

REPORT OF THE AMERICAN SURGICAL ASSOCIATION'S COMMITTEE ON FRACTURES.

THREE years ago the American Surgical Association appointed a Committee "to prepare a statement of the relative value of the operative and non-operative treatment of fractures of the long bones," etc., and a statement covering some phase of this subject has been presented at each of the three subsequent annual meetings. At the meeting this year, W. L. Estes, as Chairman of this Committee, presented a report (*Annals of Surgery*, September, 1915) based on the analysis of 1745 cases, of which 387 were operative. The Committee was greatly handicapped in these investigations by the fact that in general poor records were kept of fracture cases, so that the averages obtainable from the statistics collected (as to length of disability and other necessary data) could not be held to be conclusive. To remedy this for future investigations the Committee suggested that the record form which they had used be approved by the Association and that the American Medical Association be petitioned to put its seal of approval on it also; that all members of the Association keep records according to this form and see that they are so kept in the hospitals to which they are attached; that a copy be sent to all Accident Insurance Companies, to be embodied and incorporated in the papers given to the assured; to all Hospital Boards, with the request that these records be made a part of the routine records of fracture patients; and to various other bodies having to deal with fracture cases.

Among the findings of the Committee were: That the results are best in the age period under 15 years and that conservative treatment is generally effectual during this period; that good anatomical restitution of a fractured long bone always results in the best functional result and has the shortest period of disability; that while few open operations are reported under the 15-year age period, it seems to make little difference in the result, except in senile cases, what the age period is when the operation is done; that the end-results of operative and non-operative treatment of compound fractures show very little difference in the anatomical result, but the functional results are better after operative treatment except in compound fractures of the shafts of both bones of the leg, and here the reverse seems to be true; that there is no method or splint universally applicable, nor has any given splint or apparatus proved its superiority; that it is evident that traction methods are most frequently unskilfully employed and that as a rule too little weight is used; and that plaster casts and moulded splints are especially indicated and useful after a fracture has been satisfactorily reduced.

Among the recommendations made by the Committee are: (1) That as a general principle fractures should be treated by a skilled surgeon. (2) The *x*-ray should be employed by a competent radiographer, or a fluoroscope should be used for diagnostic purposes before the permanent dressing is applied. At least two skiagrams should be taken, and they should be taken from opposite perpendicular directions. Skiagrams should also be taken after permanent dressings are applied to prove proper reduction, and at the end of the treatment to show the result of the union and for the purpose of a graphic record. (3) Fractures should be reduced immediately after the injury, if it is possible to obtain and apply proper retaining apparatus or splints. The statistics show markedly better results when the treatment is begun at once. It is, however, not only useless but cruel to subject the patient to the pain of manipulation for reduction unless the surgeon has proper fixation apparatus at hand and the patient is where he may have a permanent dressing applied. (4) General anesthesia should be employed as a rule to facilitate reduction and prevent pain, unless the condition of the patient contraindicates it. (5) Neither the non-operative nor the operative method is to be recommended exclusively. Each has its indications and should be employed when required. Generally speaking, the age period under 15 years is that in which non-operative methods are especially effectual. In the other age periods up to 60 years operative methods may with confidence be employed when non-operative treatment has proved ineffectual in reducing or controlling the fragments in proper position. The operation should not be delayed longer than one week after the injury. (6) The open method when adopted should be employed early. It may be used at any age period, except in senile cases, whenever a skiagram shows a deformity or a position of the fragments which obviously cannot be reduced, or when proper efforts at reduction and retention have proved unavailing. (7) Some form of rigid plate applied directly to the bone or an Albee "inlay" seems to be the best fixation method in operative cases. (8) Open operations for simple fractures should be undertaken only by experienced surgeons who are thoroughly equipped by training and who have proper instruments and apparatus to meet all the possible indications of the operation.

DISINFECTION WITH DRY HOT AIR IN RAPID MOTION.

THE advantages and disadvantages of dry heat as a disinfectant agent are quite familiar. It does not injure clothing, leather, and similar materials, and colors are not appreciably affected. On the other

hand, dry heat has but slight powers of penetration and for that reason is not suitable for the sterilization of packages composed of several layers of materials or of folded garments. Although Schumburg several years ago demonstrated that penetration was increased when the heated air was kept in motion, no practical use seems to have been made of his observation. Rather recently an apparatus has been devised, primarily for the purpose of killing vermin in the clothes of soldiers, and it has proved so successful that Rautmann (*Centralbl. f. Bakt.*, 1915, lxxvii, 50) was led to test its disinfecting powers on a number of materials and under various conditions.

The apparatus consists of an electrically driven blower, which drives air through an electrically heated coil and thence into the disinfecting chamber. From here the air is returned again to the blower so that the same air is used over and over. The speed of the air current is given as 2.8 meters per second. An automatic regulator prevents the temperature in the chamber from rising too high. In its exit from the disinfecting chamber the air apparently encounters baffle plates, which offer more or less obstruction to its passage. The results of the tests were very encouraging. In every instance the organisms tested were killed, whether they were animal parasites or such resistant bodies as anthrax spores, even when they were protected by wrapping them in many layers of linen or wool. By the use of maximum thermometers Rautmann was able to demonstrate a temperature of over 150° C. in the center of a large roll of material after two hours and eleven minutes, in spite of which the material was not altered or injured in any way. Temperatures of 160° C. were often reached within an hour, and in no case did any of the material tested show any injurious effects. Rautmann apparently did not estimate the pressure under which the air existed in the disinfecting chamber, and it is possible that an increased pressure had something to do with this quite remarkable efficiency of dry heat. He did, however, measure the moisture content of the air and found that it became less during the progress of the sterilization.

These experiments greatly broaden the field of the application of dry heat for disinfection purposes. The absence of injury to material is an important factor and, although the details of construction of the apparatus are not given, the author says that it is not expensive. In the absence of electricity the blower may be driven by a gas motor and the heat supplied by a coal or wood fire. Such an apparatus might find many useful applications beside those in military life.

THE DANGERS OF BLOOD TRANSFUSION.

THERE is no possibility of denying that blood transfusion is an important method of treatment in suitable cases, and its use has probably often been instrumental in saving life. There is all the more reason, therefore, to regret the present tendency to use it on any or all occasions without regard for the proper indications. If persisted in, this practice will inevitably result in discredit to a method which has many features which should make it indispensable at times. This present tendency is no doubt due, in part, to the recent development in the technique of the operation, which has resulted in making it a relatively easy and simple procedure. It is also due, however, to a failure on the part of the medical profession to recognize the dangers which may follow transfusion in the presence of unfavorable conditions. It is true that these dangers are, in a measure, avoided by the testing of the bloods for incompatibility, but the protection thus afforded is not absolute.

Ottenberg and Thalhimer have recently published (*Jour. Med. Research*, 1915, xxxiii, 213) further results of their studies in experimental transfusion and show some interesting observations. They found no evidence of harmful effects resulting from the transfusion of iso-agglutinative blood and consider this as relatively innocuous. On the other hand, transfusion of blood which was hemolyzed by the recipient (they were working with cats) produced hemoglobinuria, intravascular phagocytosis of red cells, and often a glycosuria. The glycosuria seemed to be due to or to be connected with the formation of antibodies directed against some serum constituent. A very important observation was that when an animal was transfused several times it tended to develop hemolysins in its blood, even though the donor remained the same, and that if the transfusions were persisted in, not only were the injected red cells destroyed, but a gradual destruction of the animal's own cells began and continued for days and weeks, resulting in a pronounced anemia. Nucleated red cells appeared in the circulating blood. There was a tendency to spontaneous recovery.

One of the favorite methods of the present day, especially in cases of pernicious anemia, is the repeated transfusion of small quantities of blood from the same donor. It probably has not been the custom to perform the compatibility tests more than once under such circumstances, so that there is no information regarding the possibility of the development of hemolysins. There have been cases where such treatment seemed to have the effect of hastening the process of blood destruction in the patient, and it may very well be that in these instances the recipient developed antibodies against the blood of the donor and that one result was the increased destruction of his own cells. The possibility is certainly there, and it is essential that in the future transfusions be resorted to less frequently and with more mature consideration than in the past.

ALCOHOLIC PSYCHOPATHIES.

ALCOHOLIC insanities manifest themselves in varying forms. Such manifestations possibly to a great extent depend on the strength and kind of alcoholic beverage taken, on the susceptibility of the individual, and on the length of time over which the indulgence extends. The concentration of the beverage, too, in some degree, is a factor which governs the damage done to the nervous system. And lastly, the higher alcohols and aldehyde contained in many brandies and whiskies are thought to be more harm-

ful than ethyl alcohol. There seems, however, little reason to doubt that a defective heredity, an inherited predisposition, or a structural defect of nervous tissue provides the subject with a constitution on which alcohol acts with the most disastrous consequences. By some it is argued, and with a good deal of reason, that insanity cannot be induced by alcohol unless the subject has a taint; that is, is peculiarly predisposed.

In a paper which appeared in the *Medical Press and Circular* for October 13, Dr. Clarence G. Godfrey pointed out that while he was not prepared to go so far as this, it was significant that the subjects of alcoholic insanities usually show an unimpaired condition of those viscera which are expected to undergo cirrhotic changes in the sane alcoholic. This leads to the supposition that only those who have stable nervous organisms can drink long enough to acquire cirrhotic livers and kidneys, and that if the brain is vulnerable, it will succumb first; and on the other hand, the chronic drunkard who has usually retained his reason to the end, will generally, or at least often, show no structural change in his brain, although his other organs may be diseased.

However, as the writer truly states in defining certain psychopathies as alcoholic, the mistake must be avoided of including those disorders in which alcoholism is a symptom and not a cause of the insanity. The term alcoholic insanity must therefore be confined to those forms of mental disease in which alcohol has not only been the cause, but has so influenced the symptoms that they are in some way special or peculiar, so that the mental and bodily results are specific. Godfrey reviews all the forms of alcoholic insanities, and finally asks the question, why the same toxic agent, acting on the same organ under apparently similar conditions, produces in the one case Korsakoff's disease, in another pseudoparesis, in a third hallucinosis, and so on. Is it the varying quality of the neurones in different individuals, or of the alcohol itself, or of sociological conditions that bring about such varying results?

THE THRIFTY SMOKER.

THE clinical picture following the sudden withdrawal of alcohol in a patient accustomed to its excessive use is more or less familiar to all of us, but we are less conversant with the effects of the abrupt cessation of the tobacco habit. There are probably several reasons for this. One is that neither the public nor the medical profession has yet learned to regard the use of tobacco, even in excess, as often capable of doing serious harm to the smoker. Certainly the habit is not generally looked upon as comparable to alcoholism in this respect. Another reason is that it is rare for a devotee of this weed to forswear it entirely, even though he knows that it is doing him harm. It is true that he may cut down his customary allowance to one-half or one-third, but those are exceptions where the habit is suddenly stopped.

Such cases do occur, however, and the most distressing feature is the mental depression of the patient. This may be so great as to interfere seriously with the daily routine of his life, and he may come to the conclusion that it is better for him to risk the dangers which lurk in nicotine rather than be a nuisance to his friends and relatives. A little investigation may prevent such a state of affairs and allow the patient to resume his habit to some extent without harm. The physician should find out not only how much his patient smokes in a day, but also how he smokes. It will be soon evident that many smoke a cigar or cigarette to the bitter end. The more fastidious ones use holders, while the less particular impale the butt on a toothpick or the point of a penknife and stay with it to the last gasp.

Whether such a custom is the product of thriftiness or merely represents an all-consuming affection for My Lady Nicotine is not always easy to tell, but the effect is the same in any case. The closer the burning tobacco is to the mouth the more are its toxic effects enhanced. Nicotine (if that is what causes the trouble) is of course present only in an infinitesimal quantity in tobacco smoke, but it seems to have a greater toxicity under such circumstances; and then little or none of it is lost when the distance traversed is so small. The long pipes which we are wont to associate with phlegmatic Dutchmen are undoubtedly more innocuous than the comparatively short pipe favored by the Anglo-Saxons. Some of this latter variety, however, are made with a well or some other patent attachment, and it would seem that we should recommend these to patients who suffer from smoking. In the case of cigars and cigarettes we should advise that they be discarded when about three-quarters smoked, no matter how much agony such a course entails to the thrifty or to the tobacco-loving soul.

HYPERTONIC SALINE SOLUTION IN GYNECOLOGY.

HYPERTONIC saline solutions, Wright's solution, and others have been employed with a very considerable degree of success in the treatment of septic shell wounds, and Clifford White draws attention in the *Lancet* of October 30 to the value of such solutions in the treatment of surgical affections of the female pelvis. Since he returned to England some months ago he has used a solution made up of 4 drams of sodium chloride and ½ dram of sodium citrate to each pint of water as a vaginal douche in all inflammatory and septic cases in which a douche was required, and has found that the effect was better than that of the antiseptic douches previously employed. In puerperal cases with sloughing of the perineum and vagina the effect is said to have been extraordinary. According to White, in puerperal sepsis, especially abortion cases, after cleaning out the uterus and douching it with saline solution it is useful to leave a few tablets of salt inside the uterine cavity to ensure that any organisms left there are flooded with the serum that is drawn in to dissolve the salt. It is likewise pointed out in this paper that in or about 1905 the late Mr. Barnard advocated the use of brine enemata for abdominal cases, and White has frequently ordered them and has been satisfied with the result. Finally, attention is drawn to the fact that for the obstinate constipation of eclamp-

sia such enemata are very useful, as soap enemata may be retained and turpentine is absolutely contraindicated because of the renal condition.

Recklinghausen's Disease.

This so-called congenital neurofibromatosis attributed to disturbances of the embryonal period now falls in line as another manifestation or concomitant of disease or disorder of the hypophysis and chromaffin system. Along with the peculiar formations which appear at times over the entire integument may be seen pigmentation agreeing in every way with that of Addison's disease. There are also seen in certain cases anomalies of osseous growth, and optic nerve symptoms which point to involvement of the hypophysis. At a meeting of the Hamburg Medical Society last summer (*Deutsche medizinische Wochenschrift*, September, 23) Delbanco reported a case of neurofibromatosis in a woman of 50. One rapidly growing and painful neoplasm in the knee hollow was removed and proved to be malignant. The skin was completely covered with the growths and also deeply pigmented. Nervous cell elements displaced during the embryonal period were able in later years to give rise to ganglion cells, glia cells, and nerve fiber cells. The relation of this anomaly to the endocrine glands was, however, not made clear.

News of the Week.

Red Cross Seals.—Announcement is made by the American Red Cross that the proceeds of the sale of the Red Cross Christmas seals will be devoted this year, as in previous years, to the carrying on of the tuberculosis work in this country, and not to the war relief work of the society.

Death Rate in New York.—During the week ending December 11 the death rate in New York City was 13.66, representing a total of 1,520 deaths, or 182 deaths more than during the same week of last year, when the rate was 12.15 per thousand. Of these deaths 54 may be accounted for as due to the increase in population. The mortality from diseases of the heart and kidney was particularly heavy, 399 deaths, or 106 more than last year, being due to these causes, and the Department of Health has again called attention to the necessity for a yearly medical examination as a safeguard against these diseases.

Tooth Paste Tax.—The American Druggists' Syndicate is preparing petitions to be signed as a protest against the placing by Congress of an emergency tax on tooth paste. The petition says: "We submit that instead of taxing tooth paste and toilet preparations which contribute to human cleanliness, human comfort, and human health, the tax ought properly to be paid by those who are making profits out of the war."

Medical Supplies Freed.—The British Government has announced its decision to permit medical supplies consigned to the American Red Cross to enter Germany, the permission being contingent upon the guarantee of the United States that such supplies will be used only by the American Red Cross. The United States had previously protested against the holding up of supplies of rubber gloves needed by the Red Cross workers in Germany.

Stealing American Property.—It is reported that a troop of Bulgarians recently confiscated two carloads of flour belonging to the American Red Cross at Monastir, and when Dr. Forbes, the physician in charge, protested he was imprisoned.

Warsaw University.—The Russians have transferred the University of Warsaw to Rostow-upon-Don, while the German Government has reestablished the University at Warsaw, and has added a faculty of medicine. Professor Paszkowski, who is in charge of the academic information bureau at Berlin, has gone to Warsaw to advise on the reorganization of the university.

Liner for Hospital Ship.—The British Admiralty has taken over the White Star liner *Britannic*, of 48,000 tons gross, and has converted it into a hospital ship.

Bromide Shortage.—A tremendous recent advance in the price of bromides is the occasion of some concern, the increase being over 1,000 per cent. Bromides that before the war sold for 35 cents a pound, are now priced at $5.50, and the manufacturers report that at any price it is often impossible to obtain large quantities.

Harvard Questionnaire.—The director of the appointments bureau of the Harvard Medical School recently issued a questionnaire to 900 physicians who had graduated from the school since 1900, for the purpose of obtaining suggestions for answers to questions asked by recent graduates and medical students, and also as a part of a general movement to improve conditions for physicians and the communities they serve. The questions covered these points: What the young doctors have done; general practice or specialization; how much hospital work after graduation; how much income they have made; what was lacking in the medical school course; whether the practice of medicine has proved satisfactory. From the 600 answers received it has been deduced that one difficulty in the medical profession is that the doctors are not scientifically distributed, there being a strong tendency to remain in the large cities, and that, also, the hospitals in the city are not properly situated, so that districts often overlap. The average annual earnings of men who had been out of the medical school for thirteen years is given as $4,680; while men in their fourth year averaged only $1,835, and those in the first year only $1,237. Of the 600 only 36 reported that they had confined themselves strictly to general practice; 134 maintain general practice with a specialty; and 142 are specialists only, this number, including those who have stuck to laboratory work. Of the specialists, 90 are surgeons, 9 gynecologists, and 9 orthopedists.

Health Books for Schools.—Dr. Charles F. Bolduan, head of the Bureau of Public Health Education of the City Health Department, has prepared a list of books on health instruction, and with the aid of the public libraries these books will be placed at the disposal of the public, for circulation particularly among high school pupils. In all seventy-two books are recommended. Twenty of these come under the heading of health; four are on good food; four on food and cooking for the sick; seven on first aid to the injured; six on disease; eight on the home nurse, and twenty-three on the care of babies.

Public Health Service.—The annual report of Surgeon General Blue of the United States Public Health Service records the largest amount of work performed in the history of that service, the functions of which were largely increased by the pas-

sage of the public health law of 1912. The report lays stress on the economic importance of disease prevention. Scientific investigations of malarial infection were carried on; and studies of occupational diseases and industrial hygiene were instituted at several places during the year. A survey of industries at Cincinnati was made to determine the cause of the prevalence of tuberculosis among industrial workers; and investigations relating to the migration of persons suffering from tuberculosis were completed. Rural sanitation work was conducted in six States, resulting in the reduction of typhoid and other communicable diseases; and investigations of the pollution of streams and examinations of shellfish were also made.

Typhus in Mexico.—An epidemic of typhus fever of alarming extent is said to be raging in Mexico City, and the Carranza Government has undertaken a campaign to combat its further spread. The cases in the foreign settlements of the city are few, thirteen having been reported in the English and American colonies up to the middle of December. Among the preventive measures to be inaugurated is the establishment of a corps of sanitary police, working under the Federal Board of Health, which will oversee the cleaning of every public and private building in Mexico City and neighboring towns. Public baths and barber shops will be established; the sale of alcoholic liquors will be absolutely prohibited, and places of public amusement will be disinfected daily and forced to close each night at 11.

Journals Consolidate.—The *Physicians' Drug News and Office Practitioner* has been acquired by the Critic and Guide Company, New York, and will be consolidated with the *Critic and Guide*, beginning with the issue of January, 1916. The consolidated journals will remain under the editorship of Dr. William J. Robinson.

Americans Honored in Japan.—Dr. William H. Welch of Johns Hopkins University and Dr. Simon Flexner of the Rockefeller Institute for Medical Research have been decorated by the Emperor of Japan in recognition of their help and guidance to Japanese medical students in the United States and of their contributions to medical work in Japan. Dr. Welch received the decoration of the Third Order of the Rising Sun and Dr. Flexner that of the Third Order of the Sacred Treasure.

Aid Hospital in Japan.—President Wilson was one of many prominent persons who attended on December 13 a meeting in Washington in the interest of St. Luke's International Hospital at Tokio, Japan. Dr. Rudolf B. Teusler, superintendent of the hospital, was among the speakers.

Centenarians Dead.—Mrs. Emily M. Osborne of the Bronx, New York, who celebrated her one hundredth birthday last April, died suddenly last week.

Mrs. Rachael Josephvitch, the oldest inmate of the Harlem Home of the Daughters of Israel, died at the home on December 16, aged 106 years.

Medical Examination Day.—The Department of Health announces that the experiment of a Medical Examination Day in New York was very successful and met with a hearty response from the public. Although December 8 was the day set apart many persons called at the various clinics and offices of the department both before and after that date, and there seemed everywhere a deep appreciation of the preventive work which the department is attempting to organize.

Goats' Milk for Infants.—Through the cooperation of the Research Laboratory of the Department of Health and the Sea View Hospital, New York, the value of goat's milk in infant feeding is to be studied. As previously announced, the hospital has recently received a flock of twenty-six goats bred by the Department of Agriculture, which will permit of the feeding of 125 children at the institution. The clinical observation of these patients will be supplemented by tests and examinations made at the laboratory. An attempt will be made to determine whether the immunity of goats to tuberculosis can be transmitted through the milk to the children.

Hospital Gets Funds.—Subscriptions amounting to $250,000 were pledged on December 12 at the ninth annual celebration of the founding of the Hospital for Deformities and Joint Diseases, New York. The pledges will form the nucleus of a building fund, the cost of the new buildings desired being estimated at about a million dollars.

Fire Causes Panic.—A slight fire in the Jersey City Isolation Hospital, Jersey City, N. J., on December 15, caused a panic among the twenty-three patients, mostly children, who were with difficulty quieted by the doctors and nurses. The fire started in the cellar of the building, and because of the smoke it was necessary to carry all of the patients to a large porch at the extreme end of the building. No serious damage resulted.

Bequests to Charities.—By the will of the late Catherine J. Pryor of New York, who died on November 3, the Manhattan Eye, Ear, and Throat Hospital and the Society of the New York Hospital received $1,488.25 each, and the New York Institute for the Instruction of the Deaf and Dumb and the New York Institution for the Blind receive $1,988.22 each.

The sum of $25,000 is left to St. Christopher's Hospital for Babies, Brooklyn, by the will of the late Harrison P. Wallis of that city.

Will Not Test Autolysin.—The Board of Health of New York at a recent meeting decided not to make an official test of autolysin, which has been widely advertised as an effective treatment for cancer. The Board had been requested to make a series of tests extending over three years under the direction of a corps of specialists, but since cancer is not a communicable disease, it was felt that the expense to the Department of Health of such a long experimentation would not be justified.

Civil Service Examinations.—On January 18, 1916, the United States Civil Service Commission will hold examinations for the purpose of filling vacancies in the Philippine service, as follows:

Bacteriologist and pathologist (male), $2,000-$2,500. The degree of M.D. or Ph.D. from a college or university of recognized standing, including at least one year's training in bacteriological laboratory work, is a prerequisite. The duties of the position will be the carrying on of research work in the laboratories of the Bureau of Science, combined with routine bacteriological and pathological work, and applicants should have experience in immunity and serum therapy.

Assistant surgeon (male), $1,800. From the register of eligibles resulting from this examination certification will be made to fill a vacancy in this position in the Bureau of Science, Manila. Applicants must be graduates in medicine from a school of recognized standing, and have had in addition special training in bacteriology, either during their medical course or in postgraduate

work, and must be between the ages of twenty-one and forty.

Persons desiring to take the above examinations should apply for Form B. I. A. 2 and 2118, stating the title of the examination, to the United States Civil Service Commission, Washington, or to the secretaries of the boards in various cities.

The A. M. A. Elections Declared Illegal.—The Illinois Supreme Court on Monday of this week affirmed the decision of the Appellate Court, handed down some time ago in the suit brought by Dr. G. Frank Lydston, that the election of the American Medical Association held outside the State of Illinois is illegal. The court has, therefore, ordered the issuance of a writ of mandamus directing the State's Attorney of Cook County to bring quo warranto proceedings against the Association for the removal of the present officers.

Personals.—Dr. HENRY W. FRAUENTHAL of New York has removed his office to 160 West 59th Street.

Dr. WILLIAM OPHÜLS, professor of pathology in the department of medicine of the Leland Stanford University, California, has been appointed acting dean of the department to succeed Dean Wilbur, whose term as president of the university will begin on January 1, 1916.

Dr. HARRY FINKELSTEIN has been appointed adjunct attending surgeon to the Hospital for Deformities and Joint Diseases, New York.

The Late Dr. A. Alexander Smith.—The following minute was adopted at a meeting of the New York Clinical Society on December 17: "It is with profound sorrow that the members of the New York Clinical Society record the death of their late associate, Dr. A. Alexander Smith. Dr. Smith was one of the founders of the Society and has always been active in promoting its interests and adding to its dignity. The value of his wide experience, keen observation, and sound judgment deeply impressed all those whose privilege it was to associate with him, and his character, kindliness, and geniality exerted an influence which will be of lasting endurance among the wide circle of his colleagues. The Society directs that this minute be transmitted to the medical press and a copy be sent to the family of Dr. Smith."

Obituary Notes.—Dr. CLINTON BEECHAM KNAPP of New York, a graduate of the College of Physicians and Surgeons, New York, in 1902, a member of the New York State and County Medical Soocieties and the New York Obstetrical Society, formerly attending surgeon at the Lying-In Hospital, and assistant gynecologist at the General Memorial Hospital, died at his home in Caldwell, N. J., after a long illness, on December 15, aged 41 years.

Dr. FREEMAN HARDING HORNIBROOK of Cherokee, Ia., a graduate of the University of Illinois, College of Medicine, Chicago, in 1902, and a member of the Iowa State Medical Society and the Cherokee County Medical Society, died very suddenly at his home, on December 1, aged 37 years.

Dr. ABRAHAM T. FULTON of Mount Vernon, Ohio, a graduate of the New York University Medical College, New York, in 1882, died at his home from Bright's disease, on November 29, aged 60 years.

Dr. FRANCIS A. MITCHELL of New Albany, Ind., a graduate of the University of Louisville, Ky., Medical Department, in 1883, died suddenly at his home on November 25, aged 82 years.

Obituary.

RUDOLPH AUGUST WITTHAUS, M.D.,

NEW YORK.

DR. R. A. WITTHAUS, who died on Monday of this week, was born in this city August 30, 1846. After graduation from Columbia University in 1867 and completion of a post-graduate course for the degree of A.M., he studied at the Sorbonne and Collège de France in Paris. Upon returning to this country he took up the study of medicine, receiving his M.D. degree from the University Medical College in 1875. He was associate professor of chemistry and physiology at the University Medical College in 1876-78, and full professor from 1882 to 1898; from 1898 to 1911 he was professor of chemistry and physics at the Cornell Medical College; he had also filled the chairs of chemistry and toxicology for several years at the University of Vermont and the University of Buffalo.

Dr. Witthaus was a member of the American Association for the Advancement of Science and of various societies of chemistry in this country and in Europe. He was the author of "Essentials of Chemistry," "Manual of Chemistry," which reached its sixth edition in 1908, and the "Laboratory Guide to Toxicology." He was also the editor of "Witthaus's and Becker's Medical Jurisprudence," and contributed many articles on toxicology, chemistry, and medical jurisprudence to the Reference Handbook of the Medical Sciences and various chemical and medical periodicals. He was a toxicologist of great repute and had testified in some of the most notable murder cases in the United States.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

BRADSHAW LECTURE—NERVOUS AFFECTIONS OF SIXTH AND SEVENTH DECADES OF LIFE—RESEARCH INSTITUTE—BIRTH RATES—CANCER—ROYAL COLLEGE OF SURGEONS—NOBEL PRIZE—AMBULANCE AND FIRST AID.

LONDON, Dec. 3, 1915.

THE Bradshaw Lecture of the Royal College of Physicians was this year entrusted to Prof. Michell Clarke, who used it for the consideration of the "Nervous Affections of the Sixth and Seventh Decades of Life"; these may be classed as affecting the general nervous system or as the cerebral portion, the latter tending to increase during the period in question. That of the greatest activity of the originative and creative faculties has passed, as a rule, by the age of 50, but in the later years experience has been ripening unless disease has intruded to prevent or restrain the normal growth. The lecturer passed by meninigitis with the merest note on the tuberculous variety, and that on account of the peculiar symptoms in adult cases. When it is due to pus-producing organisms it is not frequently seen after 50, as a primary infection lumbar puncture will determine the diagnosis. As a complication of pneumonia it may be a feature of that disease or due to the one infection. In adults it is usually the termination of chronic pulmonary tuberculosis. Of 126 cases between 16 and 60 years of age fifteen occurred between 40 and 50, and only four after 50, illustrating its infrequency after that age.

Diseases of the cerebral vessels are of most importance on account of their effects on nerve tissue, giving rise to what we term nervous diseases in regard to the symptoms we are asked to relieve. But the causes belong rather to the vascular system as do the methods of prevention. Cerebral hemorrhage and thrombosis are the most common between 50 and 70; at this age the symptoms began in 7.2 per cent. of 500 cases. The nature of the growth was verified by post-mortem or by operation in 238 and the onset in them was between 50 and 70 in 9.6 per cent. The gliomata were 49.2 per cent. of the total. Carcinomata were fewer in number, but the percentage nearly 40. In another series of 485 cases from various sources the percentage at same age reached 13. In 18 cases of intracranial tumors—12 verified by post-mortem or operation—the tumor was cerebellar in 1, it was in the cerebello-pontine angle in 2, in the others variously situated. Three of the patients were over 60; in 4 vertigo was the first symptom. Diagnosis is generally difficult at first—the prominent symptoms being common in persons over 50 and of various origin. Vascular disease is suggested by mono- or hemiplegia, but a gradual onset of hemiplegia is always suggestive of tumor. Passing to cerebrospinal syphilis Professor Clark said of 261 cases 9 per cent. were over 50 and only three cases over 60; in these 60 personal cases are included in which eight were over 50. The interval between infection and the onset of nervous symptoms for the majority may be reckoned as within 10 years—many much earlier. The common statement that the older the patient the shorter is the interval is not correct. In three of the lecturer's cases the age of infection is given as 35, 44, and 46 respectively, the cerebral disease coming on from 12 to 15 years afterwards. In others late onset seems due to a long interval after infection. The symptoms do not differ much from those in younger patients. Fits indistinguishable from ideopathic epilepsy may occur, usually beginning before 50, though it appeared in a man of 60 who had had attacks resembling petit mal; another at 54 who had had many severe epileptic seizures. Syphilitic affections of the spinal cord are more uncommon than cerebral cases after 50. The symptoms come on rather early especially in meningomyelitis. Passing to the neuroses, it is commonly said that migraine tends to be mitigated in later life and though there seems ground for this opinion a prognosis to this effect in any given case cannot be safely given.

Epilepsy, too, diminishes as life advances, but it may begin at any age and great care is required to make sure that an epileptic-form fit in later life is not symptomatic of some underlying disease. Between 50 and 60 we meet with (1) cases in which it persists throughout life; (2) in which it occurred in early life, was suspended for some years and reappeared late; (3) in which the onset was after 50. These last may be connected with arteriosclerosis and high blood pressure, and so are not to be considered as idiopathic epilepsy; they may be severe or only mild (petit mal). Some are undoubtedly due to contracted granular kidney, but others not. Vertigo is sometimes a symptom and complicates the diagnosis, especially when aural vertigo attacks an epileptic, especially as it is so often due to other causes. Though the nervous affections of this period form an interesting group they are comparatively less numerous and urgent than is sometimes supposed. Paralysis agitans is characteristic and next in frequency some combined scleroses and muscular atrophies of central origin.

The first annual report of the Medical Research Committee (for the year closing on October 1) shows that the war arrested plans for research which had been drawn up and were about to be started. But others which had been initiated have been carried on, dealing with tuberculosis, relation of milk to hygiene, rheumatic infections, nervous diseases, inhalation of dust and pulmonary disease, diabetes, cardiac affections, general pathology. No subject had seemed more urgent than the pathology of infected wounds with a view to treatment. The recent battles have furnished experience of septic wounds and unsuspected difficulties met with in their management. The committee expresses gratification that their organization, though only in its infancy, has been found directly applicable and adapted to the needs of the present time. The Medical Research Fund has shown the feasibility of bringing auxiliary agencies rapidly to the service of government departments—especially to the army medical department.

Dr. Louis Parkes read a paper on the 23rd inst. at the Royal Sanitary Institute, in which he said that the birth rate of nearly all the European nations had been decreasing during the past thirty years, and it seemed certain that it would continue to decrease for many years after the war, the effect of which at present can only be a matter of speculation. Statistics give an approximate idea of the number of males of military age who after two years of war will have died of disease or wounds, or will have become permanently incapacitated. Germany from its population of 66,000,000 would have lost 2.2 millions; Austria-Hungary (50,000,000), 1.7; European Russia (123,000,000), 3.3; France (40,000,000), 1.3; United Kingdom (46,000,000), 0.5. Adding the figures of other nations (estimated) he hazarded the total destruction of life in the two years of war to have been 20,000,000. Dealing with the causes of rise and fall in birth rate, he insisted on the woman's demand for emancipation and the many occupations opened to her. The saving was in the lowest classes, and it was scarcely satisfactory for the nation to be reinforced from the least intelligent and most dependent units.

Cures for cancer are so numerous that if half the good results reported proved permanent the disease ought to be exterminated. Many cases, however, seem to survive and furnish material for more remedies. The internal administration of copper sulphate is stated by Dr. Manara in *Il Policlinico* to have cured a case of uterine cancer, of which he gives a full account, with illustrations of the microscopical appearances of portions of the cervix removed at different times. He employed daily intramuscular injections of a 1 per cent ammoniated solution of the drug, which he thinks is reduced and precipitated in the body as a sub-oxide by the glycogen of the neoplastic cells. These are killed by the caustic effect of the suboxide, and the growth of the neoplasm thereby arrested.

The annual meeting of the Royal College of Surgeons was held Nov. 18, Sir F. Eve, vice-president, in the chair. Mention was made of the efforts of the council to remedy the scarcity of subjects for dissection. Special regulations had been made to facilitate the obtaining of their qualifications by those who had completed their training and other matters connected with the war, an extra examina-

tion having been held from which an increase of membership had resulted.

The claim of members to representation on the council was again discussed, with the usual result. The president in reply to an appeal for his opinion said the objects of the college were direction of the education and examination of candidates for admission and the advancement of surgery. Some seemed to desire to make it somewhat like a trades union.

The Nobel Prize for medicine for the year closing with October has been awarded to Dr. Barany of Vienna University for his work on the vestibule of the ear.

The Governor of Hongkong reports the receipt of the sum of £450 from the Hon. Mr. Lau Chu-pak, on behalf of himself and his son, for the purchase of a motor ambulance to be presented to the St. John Ambulance Corps, together with a subscription of £163 19s 4d from some of his Chinese friends, for the equipment of the same.

All troops trained in Canada are to have instruction on first aid for the wounded, given by the Canadian branch of the St. John Ambulance Association.

Progress of Medical Science.

Boston Medical and Surgical Journal.

1. **Medical and Social Aspects of Syphilis of the Nervous System.**—Abner Post calls attention to the financial aspect of syphilis. It is the only communicable disease where the community demands that the suffering individuals shall bear the expense of protecting the community. The social conditions of syphilis are extremely interesting. The social worker has a delicate task in attempting to improve the social condition of syphilitics, and it is a matter that presents wonderful opportunities for mischief. When the social worker goes into the family of a syphilitic she must dismiss from her mind all presupposed guilt. Syphilis is perhaps the only crime in which it is taken for granted that the individual is guilty. There are a large number of innocents. Without any regard to numbers some such statement as this may be made: The innocents are too many to be ignored. The immoral are not all lost souls; some of them are to be numbered with those repentant sinners that cause more joy in heaven than those who never went astray. It is the function of social service to seek and to save rather than to judge. One must also keep in mind that the danger is confined practically to the individual whose syphilis is comparatively fresh and who has external moist lesions, so that the mere presence of a syphilitic is not by any means a source of danger.

2. **Examination and Prophylaxis for Syphilitic Patients and Their Families.**—Helen M. Wright describes the methods of investigation used by the social service department of the Psychopathic Hospital, Boston, Mass. Investigations have been projected in four directions, namely, examination, history, treatment, and education. The work suggests the following recommendations for broader methods of investigation. 1. A system by which every syphilitic house patient at the Psychopathic Hospital shall have a social history obtained from outside sources. 2. The use of the Wassermann test in suitable cases and a standardized method of recording physical stigmata for all children in the public schools. 3. A public (Board of Health) registration of all persons having a history of syphilis, either by name or by number. 4. A state appropriation provided whereby salvarsan treatment may be used for therapeutic and research purposes. 5. Methods of providing public presentations of scientific data in form which the lay public can interpret for itself. 6. A Health Center, including evening clinics, men and women's clubs, conferences, and exhibits where information under medical supervision, may be given regarding syphilis, and allied diseases, as well as other mental and social hygiene questions.

3. **Bladder Tumors in the Young.**—R. F. O'Neil considers two groups of cases, those occurring in children from one to ten years and from ten to twenty years, and a second group including those from twenty to thirty years. He finds that vesical tumors in children are of very great rarity. The majority appear before the fifth year. They are of the connective tissue type and are clinically and pathologically malignant except in rare instances. Difficulties of micturition are generally the first symptom in the absence of stricture and this should excite suspicion. Straining is common. Early diagnosis and operation offer the only hope of recovery. In the second group of cases, occurring in the decade from 20 to 30 years of age, both epithelial and connective tissue types are met. Statistics from a number of hospitals show that cancer of the bladder under 30 is a very rare condition. On the whole tumor of the bladder occurring in the young are most unsatisfactory both from the standpoint of diagnosis and treatment.

4. **A Study of Kroenig's Isthmus in Pulmonary Tuberculosis.**—Walter C. Klotz has made observations on 129 cases of clinical tuberculosis admitted to the Barlow Sanitarium since May, 1913, and of 21 controls. His findings lead to the conclusion that unless the disparity of the apical percussion field as expressed in terms of Kroenig's isthmus is very marked, it does not necessarily point to tuberculosis of the corresponding side; that such disparity is of much less significance on the right side than on the left; and that in most instances the disparity of the apical percussion fields is simply due to anatomical changes unrelated to tuberculosis.

5. **Intussusception.**—William E. Ladd cites statistics with reference to intussusception at the Children's Hospital and the Massachusetts General Hospital which show that prior to 1908 there were remarkably few cases of intussusception referred for surgical aid and the mortality was very high; since 1908 the situation has changed slightly in that there has been a larger number of cases operated upon with a mortality just under 49 per cent. This is a considerable improvement but there is room for more. In any community where the cases are brought to the surgeon late he is bound to have a high mortality. The chief problem is to educate the general practitioner to be on the lookout for this disease which is not so rare as has been supposed; to appreciate the signs and symptoms of the disease in its early stages; and to send the case without delay to a surgeon of experience in the surgical diseases of children. When this is accomplished the high mortality will be eliminated.

1. **History of Pellagra.**—C. H. Lavinder reviews the writings of Casal on the subject of pellagra which show a depth of comprehension, a wealth of assimilated experience, an accuracy of observation, an orderliness of arrangement, and a breadth of scientific spirit which is worthy of emulation by the modern medical man. Casal began to record his observations on this disease as early as 1735. His description of the erythema is quite accurate and full, and gives in some detail the characteristics of the lesion, its sites of predilection, seasonal recurrence, evolution, and termination. It is obvious that Casal had a very definite and complete comprehension of the symptomatology of pellagra. However, he pays very little attention to the gastrointestinal symptoms which in our day form so prominent a part of the disease picture. Not once does he mention diarrhea. This is remarkable since no other early author has omitted this symptom. Casal thought the cause of pellagra was to be found in the atmospheric conditions of the Asturias, the humidity, fogs, high winds, etc., and in the diet of the people. He says that the principal diet of almost all who suffer from this disease is maize and millet. He hesitates to attribute the disease entirely to this diet since he finds almost all the laborers in the province subsisted on the same diet and all did not have pellagra. His remarks on treatment are brief and to the point and his therapy does not differ much from that of our day. The restricted geographical distribution of pellagra is very sharply brought out by Casal. A review of the history of pellagra shows that argumentation and experiment have in a sense traveled in a great circle; first, poor and insufficient food, then a lack of certain definite principles in the food, then poisoned food (spoiled corn), and, through a host of speculations, back to food again, with the newer ideas of an incomplete diet and the absence of certain necessary vitamines, which on the part of the zeists, reverts again to maize.

2. **Typhus Fever.**—John F. Anderson. (MEDICAL RECORD, Vol. 88, No. 22, November 27, 1915, page 941.)

4. **Prostatisme sans Prostate.**—Alexander Randall presents a study of median bar formation as a cause of urinary obstruction and expresses the belief that although the actual obstruction is at the vesical orifice, and though the changes at this point may be as classified by Young, yet the true underlying diseased condition and its pathological transformation are in the prostate. Accordingly it must be granted that these prostatic changes constitute the ultimate pathological condition, and by reason of their close apposition to the bladder orifice cause like alterations to take place in the tissues at the orifice from which the obstruction occurs. This presents a working basis for further elaboration, while the idea that the changes, as found by urethroscopic excision of the small obstructing portion, constitute the disease in its entirety, presents no explanation of why alterations take place at this point alone. The writer firmly believes that a careful analysis of the cases of true bar formation will show in every instance underlying changes in the prostate of a similar character and of etiological significance, and he especially draws attention to the close similarity of symptoms of this type of bar formation to that of the well known condition of prostatic hypertrophy. In neither condition are there any clinical symptoms until obstruction to urination occurs. After discussing the various methods of treatment the author expresses the opinion that the method of choice in the future will be one that can hardly be classed as excision or incision of the bar, but rather a destruction of the obstructing portion by means of the high frequency fulgurating current. This was performed by the repeated application of the spark through the ordinary catheterizing cystoscope and gives promise of doing away with a more dangerous and a more radical operation.

5. **Dislocation of the Semilunar Bone.**—Edwin L. Bebee finds that the ratio of this dislocation to all others and to Colles' fracture is nearly one to twenty. It is usually caused by violence of rather a severe degree and is most common in males in the active period of life. The symptoms, after a history of a blow on the back of the wrist or a fall or blow in the extended hand, are pain and inability to use the hand. Pain is referred to the wrist but may radiate to the fingers in the distribution of the median nerve. The disability is marked. The attitude is peculiar, the wrist being held rigid with the fingers partly flexed. There is apt to be some silver fork deformity as in Colles' fracture. There is a depression in the back of the wrist due to the absence of the semilunar bone from its normal position. The *x*-ray is necessary for diagnosis. The writer finds the results, in recent uncomplicated cases, of reduction by manipulation, followed by fixation, good. If this is not successful open reduction should be attempted. In all cases of four weeks' standing or longer the treatment indicated is excision. The writer reports a case treated successfully by open operation.

7. **A Nontoxic Antiseptic.**—Douglas H. Stewart says that from letters of inquiry that have reached him there is a demand for something in the way of wound treatment which will be cleansing, non-toxic, non-irritant, antiseptic, and yet not affect healing adversely. Two powders are suggested for the purpose of making two solutions, one for wound cleansing and one for dressing purposes, though one may get good results from the two powders mixed in a single solution. The first contains table salt and sodium citrate (10-1), and the second is a mixture of equal parts of sodium perborate and of sodium bicarbonate. If the latter solution is employed to cleanse wounds and the former is used to soak bandages, results seem almost uniformly good whether infection is present or not.

9. **Chauffeurs' Knee.**—Gustav F. Boehme calls attention to this ailment which occurs in those who drive automobiles to excess or those who are not accustomed to this form of sport. Examination shows that the knee, usually the right one, is painful and that there is limitation of flexion and extension. On each side of the patella a fluctuating swelling, of more or less extent, can be noted. The picture is one of bursitis of the subtendinous bursa lying between the tendinous expansion of the quadriceps and the periosteum of the patella. The process differs from that of housemaid's knee in that the superficial bursa is uninvolved and no swelling is felt in front of the quadriceps tendon in movement. What has been rather surprising is that in none of these cases has there been any sign of inflammation in the ankle joint or in the tendons crossing it. The treatment consists in cessation from driving, rest for a short time, and local applications of aluminum subacetate or lead and opium solution. Passive movements with baking and massage should be begun early.

1. **The Economic Waste of Sickness and Premature Death.**—Norman Bridge says that with increased longevity, life is easier, and easier because of it. The annual cost of illness and death in the United States is conservatively placed at $460,000,000, to which may be added $500,000,000 for loss of earnings by the victims. Economic reasons, though less frequently referred to than others, are the most vital reasons of all for keeping well. Measures which have brought down the death rate and increased the average longevity are improvement of the milk supplies of cities and towns, the use of diphtheria antitoxin, improvement of water supply for urban and rural populations, the destruction of mosquitos, tenement house inspection, regular inspection of schools by experts, scientific midwifery among the poor, visiting nurses for ordinary sickness, vaccination against smallpox and typhoid fever, pure food and drug laws, partial suppression of the use of alcohol, fresh air and outdoor sleeping, athletics among young students, the care of tuberculous patients, and the cure of hookworm. Some of the things that are to be hoped for which will still further minimize sickness and increase longevity are: (1) More educated health officers and more education for them in universities; (2) improvement in the hygiene of rural life and the rural schools; (3) the early and late teaching of the value of keeping the body up to normal vigor all the time; (4) more vigorous campaign against flies, mosquitos and vermin; (5) a larger effort to lessen the spread and havoc of venereal diseases. Finally, the promise of a further reduction of the death rate lies in the more efficient use of the knowledge which research has given us and in the new knowledge which further research is bound to bring us.

2. **Physical Examination and Regeneration of Employees.**—Sidney M. McCurdy states that there is an advantage to be gained by industries in this country entering the field of medicine by means of the physical examination of employees and depends on the attitude assumed by medical advisers and by the captains of large industrial organizations. He describes the method of making the physical examinations of employees and supervising sickness at the Youngstown Sheet and Tube Company, where about 8000 men are employed. In the conduct of the examining department they use medical graduates who devote their whole time to the company's work. To properly understand his duty in this work the physician must have a fairly clear vision of its relation to the individual, to the industry and to society. In the regenerative work they try to eliminate all appearances of paternalism and a possible result, pauperism, by making the patient bear part of the expense of making him a useful member of society. Finally, the author discusses the question as to what is to become of the rejected and the unfit. He believes it is better for society if it can see the cost of the burden of the unfit than if the debt is concealed as we now have it. This bill to the community should be borne by all, and there is no better way than state insurance, which makes a man while well contribute toward the cost of care for society's infirm. If it is fair for the State to insure against incapacity due to accident, it is right that it should insure us against sickness and incapacity due to old age.

3. **Occupations and the Venereal Diseases.**—William F. Snow points out that there is increasing evidence in support of recognizing social and moral hazards of industry as well as health hazards. Venereal diseases illustrate a group of diseases not directly related to industrial health hazards, but closely related to the moral and social hazards of occupation. Certain industries are so conducted that young men and women are required to associate under conditions calculated to deaden ambition and self-respect, to arouse sex impulses, break down moral protection, preclude marriage, and eliminate home influences, thereby placing a premium on promiscuous sex relations and the contractions of venereal infections. In such ways industry plays a large part in the problem of venereal disease dissemination. The lines of warfare on venereal diseases as a menace to industry and to society at large present four important lines of attack, the medical, the educational, the environmental, and the moral. In all of this the physicians, and the industrial leaders among both employers and employees, have a part to play.

4. **Sickness Insurance.**—B. S. Warren believes that to meet the requirements for the relief and prevention of sickness in the United States, a sickness insurance law could be enacted by Congress to apply to all industries in the United States, or by State legislation to apply within the States. He presents a plan for such insurance based on an examination of the most successful European governmental systems of sickness insurance, and of the principles and methods practised by mutual benefit societies, trade unions, and industrial establishments in this country. A governmental system of sickness insurance similar to those in successful operation in Europe will enable the physician to receive pay for his practice and hospital work among low-paid wage-earners and will allow the patient to receive prompt and proper treatment without forcing him to become a ward of charity. It will strengthen the economic independence of the worker and at the same time greatly increase and stabilize the income of the physician, as well as enable the medical profession to carry on more effective preventive work.

5. **Roentgenographic Appearances in Rickets.**—Robert W. Lovett reports the results of a study of between 500 and 600 roentgenograms of children having rickets and found between 6000 and 7000 roentgenograms from the records of the Children's Hospital in Boston. The radiographs were studied from two points of view, (1) to establish and classify the Roentgen appearances of the acute, subacute, and convalescent phases of the affection, and to define the finer bone changes associated with the disease, and (2) to determine definitely those points in differential diagnosis by which rickets might be distinguished from such diseases as osteomalacia, scurvy, congenital syphilis, and similar affections. From this study the writer finds that in rickets constant changes are to be found while the disease is active, and are located most markedly in the epiphyseal end of the shaft. The most important of these changes are: (1) delayed ossification and indistinctness of the epiphysis, (2) fraying out of the end of the shaft next to the epiphyseal line, (3) broadening of the end of the shaft next to the epiphyses, (4) cortical thickening on the concave side of curved bones, and (5) areas of diminished density in the bone shadow of the shaft.

Periosteal thickening and multiple fractures often occur in the acute stage of the disease.

7. **Mouth Infections.**—Anna Wessels Williams, Anna I. von Sholly, Caroline Rosenberg, and Alice G. Mann present a study undertaken for the purpose of finding out how many children are infected with ameba and at what age these organisms appear in their mouths, the conditions of the mouths showing amebas, the types of amebas and their relation to the diseased condition of the children's mouths and the necessity and worth of preventive measures. Thus far 1,678 children between the ages of five and fifteen years have had a preliminary examination. They found very few children with healthy gums and sound teeth; about one-half of the number showed unhealthy gums. The study has brought out the following points: Amebas are demonstrated irregularly in all mouths once showing them, most constantly and in largest numbers in mouths showing gingivitis, least so in healthy mouths. With ordinary teeth cleansing methods, the number of mouths showing amebas is reduced one-half. With emetin in the tooth wash, the number showing amebas is greatly reduced, only about 10 per cent. showing them. The second set of controls—those doing their cleaning *at home* by ordinary methods—continue to show amebas in about 75 per cent. of the cases. The question as to the amount of emetin to be used has not yet been settled. We began with a 1:200 solution, then reduced it to a 1:400 strength. Probably a much smaller amount would be sufficient to keep down the development of the amebas. The writers hope by combining these practical investigations with laboratory studies that they may be able to demonstrate the relationship of these amebas in mouth infections.

12. **Vaccine Treatment of Gonorrhea.**—Carl C. Warden presents the results of the treatment of gonorrhea with gonococcus fats which he says are to be regarded as tentative. The cases treated thus far comprise acute, chronic, simple and complicated in men and infant girls. In all the subcutaneous inoculation of the fats has been followed by marked improvement and in some by undoubted cure. The chronic cases with posterior involvement and with slight but constant discharge containing gonococci in smear and culture have shown disappearance of the cocci in the discharge and symptoms in from one to three inoculations. The acute cases taken within the first forty-eight hours of the discharge showed complete disappearance of the cocci in smears and cultures and entire absence of the discharge within a week following one inoculation. Between these extremes are those cases showing well established infection, copious discharge, and considerable edema, which have required more frequent inoculations with increasing doses and which constitute an improved but unfinished series. There has been a slight reaction in the subcutaneous tissues, which quickly subsides. In some instances the constitutional reaction characterized by chilly sensations, anorexia, and some fever appeared in some six to eight hours. This reaction has not been constant, but is followed by marked clinical improvement. The coincidence of the disappearance of the cocci and the constitutional reaction together with his experience with anaphylaxis in animals following the administration of fresh gonococcus autolysates, or following lysis of whole cocci *in vivo*, has led the author to infer that the relation in question may be due to the sudden lysis of the cocci in the body of the patient.

1. Observations on the Common Intestinal Protozoa of Man: Their Diagnosis and Pathogenicity. C. M. Wenyon.
2. The Recognition and Isolation of the Meningococcus in the Nasopharynx of Cerebrospinal Fever Contacts. James McIntosh and W. E. Bullock.
3. Double Episiotomy During Labor. John Phillips.
4. The Nitrogen Balance in Diabetes Mellitus and Its Importance in Treatment. P. J. Cammidge.
5. Ophthalmic Notes in a General Hospital in Egypt. C. Wynn Wirgman.

1. **The Common Intestinal Protozoa of Man.**—C. M. Wenyon says that at a time like the present, while there is a great influx of individuals into England who have been residing for a longer or shorter period in tropical or subtropical countries, certain types of infection which only come to the notice of those interested in tropical medicine are likely to be encountered and that hence a description of these protozoa and of the methods of their identification is important. He describes the *Entamœba histolytica*, *Entameba coli*, and *Amœba limax*, and the flagellates, *Trichomonas intestinalis*, *Tetramitus mesnili*, and *Lamblia intestinalis*. He has seen a good many instances of protozoal infections of the gut in cases returning from Gallipoli in hospitals, both in London and the provinces. *E. coli* is very common in these men and also the three flagellates above mentioned. No case of Balantidium infection has come under his notice, but the vegetable organism, blastocystis, occurs in large numbers of these cases, while occasionally a small ameba of the limax type is seen. The writer describes in detail his method of making examinations and finds that the intestinal protozoa are best examined fresh and living and so soon after leaving the body as possible. The encysted forms, which are the carriers of infection, do not change and can be satisfactorily studied days after they have been passed, but the unencysted motile forms quickly change and degenerate so that after some hours it may be a matter of great difficulty to identify them. On the whole treatment with emetine has given satisfaction.

2. **Meningococcus Carriers.**—James McIntosh and W. E. Bullock present a study made during the recent outbreak of cerebrospinal meningitis. Altogether over 2,000 throats were examined for meningococcus, and of actual contacts 5.5 per cent. were found to have meningococcus in their throats. In the various series examined the percentage of positive results varied from 0 to 25; the highest figures were only found when the epidemic was at its height and where there was considerable overcrowding and therefore a close association between patient and contacts. From this study the writers are convinced that meningococcus carriers are less frequent than is generally believed. After an extensive trial of a number of different media the most satisfactory one was found to be the following: Nutrient 3 per cent. agar, 3 parts; horse serum, unheated, 1 part. The nutrient agar should be neutral to phenolphthalien and made from beef broth. On this medium the meningococcus will grow with great rapidity, and after having undergone one or two subcultivations will live several weeks without further subculturing. However, this procedure is not quite all that could be desired. The greatest difficulty lies in distinguishing the meningococcus from certain strains of micrococcus flavus. The differential diagnosis in a certain number of cases rests on a slight difference in color. In the experience of the writers none of the strains of meningococcus isolated by them from the cerebrospinal fluid of actual cases produced the slightest trace of a yellow color; in all the color was a distinct pearl gray. The whole subject of meningococcus carriers seems to require a thorough investigation.

3. **Double Episiotomy during Labor.**—John Phillips expresses the opinion that the value of this measure of preventing perineal lacerations is not sufficiently rec-

ognized. He describes the technique of the operation, emphasizing that the proper incision is one at right angles to the vulva, since this affords more expansion and no danger, and is situated where the anterior and posterior vaginal walls fall together. During the past fifteen years the writer has performed this operation 156 times. In 118 cases the patient was in labor for the first time and in the other 38 she had either an unreduced occipitoposterior presention, a much scarred and undilatable perineum, the child head was unusually large, or the after-coming head required rapid delivery to prevent still birth. In none of these patients did any untoward symptoms arise. The indications for the operation are: 1. An exceptionally large head. 2. A long and rigid perineum. 3. Atresia, congenital or acquired, of the vagina. 4. A threatened central rupture of the perineum. 5. An unreduced occipitoposterior presentation, where restitution is impossible. 6. In breech cases in which the after-coming head has to be rapidly delivered owing to threatened stillbirth of the child. 7. A narrow pelvic arch, as is present in the "male" type of pelvis.

4. **Nitrogen Balance in Diabetes Mellitus.** — P. J. Cammidge shows how it is possible by systematic and complete analysis of the urine, when a patient is taking food of a known composition, to work out a diet exactly suited to the metabolic defects of the case instead of attempting to make the patient fit some stereotyped diabetic diet. He points out that defective utilization of the carbohydrates is not always the most important feature of glycosuria or of diabetes, and that faults in the metabolism of proteins and fats may be the cause of more serious symptoms. He, therefore, advised that greater attention should be paid to such defects and describes in detail how the "nitrogen balance" for determining the way in which proteins are being utilized can be worked out. According to his observations it is impossible for a case of diabetes to improve until nitrogenous equilibrium has been established.

1. The Goulstonian Lectures In Spinal Injuries of Warfare. Gordon Holmes.
2. Malignant Tumor of the Kidney. An Analysis of Some Symptoms and Signs of a Series of Cases. R. J. Willan.
3. An Easy Way of Detecting *S. Pallida* and Other Spirochetes. Alfred C. Coles.
4. A Simple Method for the Cultivation of Anaerobic Organisms. Lyn Dimond.
5. Ophthalmic Notes in a General Hospital in Egypt. C. Charles A. Morton.

1. **Spinal Injuries of Warfare.**—Gordon Holmes classifies injuries of the spinal cord roughly into direct injury, contusion, and concussion, and makes observations with reference to the symptoms produced by these different types of spinal injuries when different portions of the cord are affected and to the medullary lesions to which they are due. In a number of cases the histological changes have been studied. It is obvious that these irregular and diffuse changes which are found in the various types of spinal injury must be taken into account in interpreting and estimating the significance of the clinical symptoms. The structural lesions in the spinal injuries of warfare are rarely sharply limited or circumscribed, and cannot be compared to those produced experimentally in the laboratory. The level of the lesion as indicated by the clinical symptoms, for instance, often does not correspond with the level of maximal damage. The lesions are so irregular in distribution and severity when the spinal injury is not complete that much care is necessary in drawing conclusions from the clinical symptoms alone on the functions of parts which it may be assumed have been involved. Secondary changes may occur later in the cord which can alter or modify the clinical symptoms. The most striking secondary change which the author noted was the development of cylindrical cavities which are described.

2. **Malignant Tumor of the Kidney.**—R. J. Willan analyzes a series of cases with reference to (1) age, sex, side, onset of symptoms, (2) association of pain, hematuria, and a palpable renal tumor to each other during illness. He also discusses some complications and cites illustrative cases. Excluding children he finds that 63.2 per cent. of the cases occurred between the ages of 45 and 65. Of the series 63.8 per cent. occurred in males. The separate symptoms of painless hematuria, symptomless flank swelling, acute renal colic, and chronic renal pain, account for the onset symptoms in 82 per cent. of the cases. The commonest onset symptom was painless hematuria. In 32 out of 52 cases hematuria and a palpable renal tumor were associated at some stage during the illness. In three (3) cases a varicocele was a complication, that is the condition was inoperable when first seen. Two of the patients suffered from clot retention of urine and in several cases these were marked evidences of a chronic nephritis.

3. **An Easy Method of Detecting Spirochetes.**—Alfred C. Coles describes a method of detecting spirochetes as easy as that of detecting tubercle bacilli in the sputum. It depends on the following principles: 1. That structures that are colored with a fluorescent dye, when examined on a dark ground stand out very prominently while blue stained structures are very inconspicuous. 2. That if the medium in which the red stained organisms be of very low refractive index, they are exceedingly conspicuous by dark ground illumination and can be detected with a comparatively low power, but if mounted in balsam, cedar oil, parolin, or water, they are only seen with the greatest difficulty. The method briefly consists in examining a film containing spirochetes, stained in the usual way with Giesma or Leishman's stain, dry, not mounted in any medium with dark ground illumination, and using a dry lens of medium power. The author considers a number of details which very considerably simplify this problem.

5. **Treatment of Wound Infections by Antiseptics.**—Charles A. Morton takes issue with a number of statements made by Sir Almroth Wright with reference to the value of antiseptics in wound infections. He thinks that Sir Almroth Wright is not in the least justified in stating that the antiseptic treatment of wounds has completely broken down, that antiseptics are not necessary because the resistance of the tissues is sufficient to deal with infection if the wound is kept by the surgeon in a favorable condition, and that although antiseptics have the power to kill microorganisms in the laboratory they cannot act efficiently in contact with the tissues of the body. The writer pleads for further attempts on the lines practised and advocated by Carrel and urges that we should not rest content to depend on the resistance of the tissues, nor on saline irrigation to rid a recently infected wound of organisms, but should freely apply, for a considerable period, either hypochlorous acid in 0.5 per cent. or hypochlorite of soda solution. These antiseptics in a strength potent enough to kill microorganisms will do no harm to the tissues. The writer also thinks that Sir Almroth Wright's suggestion that physicians should now take charge of the treatment of wounds will be read with some astonishment, and he questions whether it is correct to assume, as some do, that the surgeon's only business is with the knife.

Münchener medizinische Wochenschrift.

October 26, 1915.

Treatment of Unilateral Weak Sight.—Heine states that the sight of one eye may become enfeebled by disease or accident, in addition to which there is a congenital weak sight, which in most cases might be found to be acquired; for there may have been a voluntary suppression of the optical compressions. In such cases there is hope for improvement by exercising the defective eye. A case is cited of a ten-year old boy who found that the vision of one eye was becoming weak in reading tests. By the use of glasses and exercises the functions of this eye had been greatly improved. The subject is now fifty-seven years, his right eye being normal, allowing for presbyopia. The left eye has vision less than 1/10, with correction for presbyopia. Since his experience with this case the author has made a study of many cases of so-called congenital weak sight and found that almost without exception there was some response to treatment over and above mere correction by glasses. The best of the latter are often inferior to the use of the stenopäic aperture or fissure, which can sometimes double the acuteness of vision—as 6/36 increased to 6/18. In a bilateral case with vision R 6/36, L 6/18 the use of a double vertical fissure raised the acuteness to R 6/8, L 6/12. Congenital weakness is often accompanied by hyperopia due to short axis of the globus. It is better to regard an eye which lacks 8 D. of emmetropia as a —8 corrected by 8 plus glasses; just as when a normal eye is made hyperopic by —8 glasses.

Neosalvarsan in Tertian Malaria.—Vandenhoff, incited by the results published two years ago by Baetger has been treating malaria in Russian prisoners and German troops with intravenous injections of neosalvarsan. There is no doubt that plasmodium carriers were introduced into the Russian prisoner camps, for some of the men confessed to having had malaria. When mosquitoes were due these carriers were isolated with screening material. But few cases of malaria developed, and most of these were tertian in type. No diagnosis was made unless the plasmodium was found in the blood. Fifteen of the patients were treated with neosalvarsan. The results were all that could have been asked, but perhaps not superior to those from quinine. The chief indications, then, are quinine intolerance and in cases which are refractory to quinine.

Infection of the Fingers and Hands of Physicians.—Heidenhain states that during thirty-one years in which he has practised surgery he has been injured innumerable times and in all customary ways, in the course of operation on subjects with sepsis and had never once become infected. He began after a while to regard himself as immune. However, with a rich experience he had never seen a surgical infection in any colleague or assistant in his own sphere of influence. Nevertheless he has seen numerous infections in surgeons from other clinics. The author's only prophylactic after an injury was to keep the hand and arm in complete rest for twenty-four to forty-eight hours. Once a colleague came to him for a dressing for an autopsy wound, and he ordered immobilization. Returning from an absence of several days he found the man dead. He had removed the dressing and very soon after experienced a chill. The author believes firmly that immobilization for forty-eight hours after these traumatisms would result in a great reduction of morbidity and mortality among surgeons. At the last moment the author had a most corroboratory test of his theories in his own person. After one day's immobilization, following an injury he felt it his duty to do a certain amount of typewriting. He soon developed a chill and local infection which laid him up for a month and caused him much misery. He was fortunate in escaping a general infection.

Explanation of Sudden Death in Angina Pectoris.—Hering recalls the fact that Heberden—who devised the name for the affection in question—declared in 1768 that its most common termination is sudden death. This holds good today, yet we are unable to state the rationale. The very rapidity of death makes it impossible to give the sequence of the lethal factors. It is necessary to know the exact time required for death to occur, for, in general, secondary death by the heart may occupy hours as well as minutes. When an embolus is formed in a coronary artery death is readily understood, but the author has conducted eight autopsies after sudden death in which no lesion whatever was found. Such cases could be explained by ventricular flutter, and as far as is known at present by no other means. In 1889 McWilliam advanced the belief that in many cases of sudden death a myocardial fibrillation could be invoked as the efficient cause; but only recently have animal experiments given some corroboration to this view. Such a theory does not connote the presence of angina pectoris in man, but only that in the latter condition the factors for producing myocardial fibrillation may be present. The most common anatomical find in angina pectoris is sclerosis of the coronary arteries. In this condition the heart may do ordinary work for long periods but is unequal to special demands upon it. At a later period it cannot perform ordinary work because it has become permanently anemic. It has been asserted, however, that anemia alone, whether of gradual or sudden origin, does not cause sudden death unless some other—at present unknown—factor is present. This might well be fibrillation, but experiment has not shown that coronary obstruction and fibrillation combined can necessarily cause sudden death. Fibrillation may be conditioned by various factors, and stands in direct relationship with heterotropic irritation of the heart. Coronary occlusion also gives uncertain results, showing that further predisposition is to be reckoned with. There is more or less confusion concerning what factors are predisposing and which are eliciting—as in the case of ischemia, for example, which can be interpreted now one way, now the other. Let us for a moment suppose that coronary sclerosis is the predisposing factor, what are the eliciting factors? These may differ much among themselves. Small emboli are commonly seen in autopsies in the substance of the heart but are not deemed sufficient as an exciting cause of death. They are known to produce small infarcts. It is, however, possible that in some predisposed cases these emboli can excite fibrillation. In experiment a disposition to the latter may be caused by hemorrhage, suffocation, narcosis, etc.; a very slight mechanical irritation may now elicit the fibrillation; or instead of a mechanical irritant, it may be a rise of bloodpressure, an extrasystole, an excitation of the extracardial cardiac nerves, etc. The ischemia of the heart which is reckoned as a constant, may also be due to various causes. The chief cause seems to be a vasoconstriction. Here tobacco may be a factor, and we know how vasodilators can overcome the condition. Many outside factors can contribute as muscular exertion, psychic factors, large meals. Our knowledge may be summed up thus far as follows: the inevitable cause of death involves an ischemia of the heart, and a myocardial fibrillation. "Fluttering heart" in common speech does not refer to

the latter but to a tachysystole. In true fluttering the heart is first arrested before it undergoes fibrillation. But a high grade of tachysystole often occurs in angina pectoris. Not until the mode of cardiac death can be registered by electrocardiography can we expect to understand its true mechanism.

A Fertilizing Coitus: When Does It Take Place?—Siegel calls attention to the unusual opportunities offered by the present war to investigate this subject. A soldier is allowed a brief visit to his home, during which he is supposed to have sexual relations a certain number of times. Failure to conceive must depend to a certain extent on the part of the menstrual cycle in which his wife claimed to be—premenstrual, postmenstrual, or interval. The duration of the furlough is from two to eight days. With records of many cohabitations traceable to leave of absence it is possible to plot striking curves, which show that by far the greater number of conceptions occur during the first eight days after the menses. From the eighth to eighteenth day after menstruation is over the curve drops steadily to 0. Finally, from the eighteenth to the twenty-fourth day after the menses no fecundating coitus occurred. This agrees with findings in peace and appears to show that in the eight days preceding menstruation a woman is relatively sterile. The great frequency of conception after menstruation must of course depend on something which occurs during that condition. Failure to conceive just before the menses may be explained by the swelling of the mucosa of the uterus and tubes which prevents the ascent of the spermatozoids. A further study of the curves with reference to the date of rupture of the Graafian follicle, as estimated, goes to show that this phenomenon must play a rôle in a fecundating coitus, the latter being most likely to occur two days before the rupture.

Chemical Diagnosis of Acute Benzol Poisoning.—Schmitz recalls the recent efforts by Heffter to demonstrate traces of benzol in cadavers. Soon afterwards Joachimoglu reported progress in this direction and the author has been able to corroborate his finds on human subjects in which benzol had been swallowed. A patient was taken to the hospital from his residence on the afternoon of July 13 of this year. He was nearly out of his head and made violent movements with wide excursions. His clothing was covered with feces and vomitus. The right side of his body appeared to have been burned in many places. The surface was pallid and cold. He breathed with loud rattling sounds and showed slight cyanosis. Pulse hardly palpable. Marked bilateral myosis. No distinct reaction to light. Breath smelled strongly of benzine, rubber, and gas. Death took place in the evening. The patient admitted drinking bedbug poison. The immediate autopsy finds were more or less confusing; for example oil drops were noted in the enteric contents. The latter were isolated and distilled and a light water white oil passed over. After repeated manipulations benzol was finally isolated in the pure state. The brain was now sent to a special laboratory, where eventually dinitrobenzol was distilled from it. It thus appears that when benzine is drank it reaches the brain within a few hours. After an examination of the intestinal contents, therefore, the brain should be analyzed, in making out a case of acute benzine poisoning, *per os*.

Etiology of Weil's Disease.—Huebener and Reiter explain our lack of knowledge of this disease by its great infrequency. Only here and there is there a cumulative incidence. In 1911 Hecker and Otto opposed the view of an ordinary bacterial transmission; the virus was ultravisible and probably depended on an insert host for transmission. The present authors believe that they have "rent the veil" in causing in guinea pigs, by inoculation, a condition quite analogous to Weil's disease in man. As is well known, few diseases so parallel each other as yellow fever and Weil's disease; the latter, in fact, being known as the "yellow fever of the temperate zone." Since yellow fever is now known to be a mosquito borne disease, it seems plausible that Weil's disease should have a like origin. The authors for the present withhold the publication of their data on this phase of the problem. For the present we know that it is an infectious disease, the living cause of which for a time circulates in the peripheral blood, and is then inoculable into the peritoneal cavity of the guinea pig. The latter develop in typical fashion fever, emaciation, albuminuria, bile pigment in the urine, nose-bleed, petechiæ, conjunctival hemorrhages, pronounced icterus of the scleræ, skin, and mucosæ. Autopsy shows that the icterus is almost universal in the deeper structures as well. The disharmony of the finds in transmission of the disease to different animals gives rise to the belief that the living cause can be active in various developmental forms.

Old and New Problems of Nursling Tetany.—Klose calls attention especially to functional spasms known as nursling tetany, spasmophilia, etc. This generic conception included both general spasms and laryngospasm, carpopedal spasm, etc.; thus leading up to a belief in the spasmophilic diathesis. Thus Finkelstein has described a constitutional anomaly which consists in a persistent mechanical and electrical overexcitability of the entire nervous system. The author devotes much argument to demonstrating that anodic excitability is a subordinate phase of general galvanic overexcitability. In other words anodic excitability stands in some definite relationship to latent tetany; while cathodic overexcitability is encountered in seemingly normal children, in the winter and spring months, who do not develop convulsions. But anodic overexcitability at these seasons is even more manifest. In fact the relationship of overexcitability to latent tetany and actual convulsions is very complicated. In regard to mechanical overexcitability the facialis phenomenon is often negative in the subject of nurslings' tetany, and certainly bears no relation to electrical excitability. Nevertheless a positive facialis phenomenon is *prima facie* evidence of latent tetany. The socalled peroneus phenomenon is still more common, and occurs in both latent and manifest tetany—in fact it is positive in 97 to 98 per cent. of all cases. Both of these induced symptoms decrease in significance with oncoming years until within a short time, they cease to possess any diagnostic value. The author places his chief reliance on the electrical reactions, using the mechanical tests for confirmation. The bridge between tetany and rickets is believed to comprise the possibility of tetany of the nonstriated muscles. For example, the bronchial spasm which occurs in tetany and rickets may be regarded as a bronchotetany. This subject is relatively new and further study of it is necessary.

The Predestined Bald Head.—W. Knowsley Sibley says that if a seborrheic patient is going to be bald in middle life or even old age, the symptoms of alopecia will show themselves between the ages of fifteen and twenty-five years. Although the hair may gradually become thinner as years advance, it is very unusual for a severe form of baldness to begin after this period of life. —*The Practitioner.*

Book Reviews.

A Synopsis of Medical Treatment. By George Cheever Shattuck, M.D., Assistant Physician to the Massachusetts General Hospital. Second edition, revised and enlarged. Boston: W. M. Leonard, 1915.

As the title implies the "Synopsis of Medical Treatment" is a brief description of the most approved methods of treating disease medically. Dr. Shattuck has provided a sufficiently satisfactory résumé of various modes of medical treatment expressed in concise language as well as a synopsis of important and valuable drugs and non-medicinal preparations. The work supplies a ready handbook of medical treatment and should be useful in a high degree.

The Medical Clinics of Chicago. Vol. I, No. 2 (September, 1915). Published bi-monthly. Price, $8.00 per year. Philadelphia and London: W. B. Saunders Company.

The second number of the Medical Clinics presents about the same amount of material in the same space as the first number, that is twenty cases in less than 200 pages. There is in addition an excellent contribution from Pusey on the treatment of superficial epithelioma by the *x*-ray. The discussion of stomach conditions by Mix and of cardiac irregularities by Hamburger are well worth while. The number is marred by several errors that should have been corrected by more careful proofreading, for example, Kernig's sign is not elicited by flexure of the leg upon the thigh (p. 211), nor is a decinormal permanganate solution "of the same strength" as a normal oxalic acid solution (p. 230). On page 325, in discussing the use of neosalvarsan, one author is made to say "give 1.10 mm. at a dose." This is a direction which it is difficult to interpret. Many of the cases receive but scant consideration, but in the instances above mentioned the discussion is very satisfactory. This number is an improvement over the first one.

Ophthalmoscopic Diagnosis for General Practitioners and Students. By George W. Jean, A.B., M.D., Instructor in Ophthalmology and External Diseases of the Eye in the School of Ophthalmology of the New York Eye and Ear Infirmary, Assistant Surgeon to the New York Eye and Ear Infirmary, Instructor of Ophthalmology in the University and Bellevue Hospital Medical College, and Attending Ophthalmologist to the College Clinic, Ophthalmic Surgeon Williamsburg Hospital, etc. Sixty-eight Illustrations. London, New York, Paris: E. B. Meyrowitz, Inc.

This small volume of 123 pages gives an outline sketch of the subject, in terse, colloquial language, and is very fully illustrated in black and white. The first chapter describes the technique of ophthalmoscopy; subsequent chapters are devoted to descriptions of the normal and pathological conditions of the fundus and interior of the eye concerned in ophthalmoscopy. The book is quite well designed to fill the purpose for which it was written, provided the purchaser wishes an elementary knowledge of the subject only.

Handbook of Medical Entomology. By Wm. A. Riley, Ph.D., Professor of Insect Morphology and Parasitology, Cornell University, and O. A. Johannsen, Ph.D., Professor of Biology, Cornell University. Price, $2.00. Ithaca, N. Y.: The Comstock Publishing Company, 1915.

The Handbook of Medical Entomology is based on a course of lectures along the lines of insect transmission and dissemination of human diseases given in the department of entomology of Cornell University during the past six years. The authors aim to give a general survey of the relation of insects to disease and to put the student of medicine and entomology in touch with the discoveries and theories which underlie some of the most important modern work in preventive medicine. The text is well illustrated and a lengthy bibliography is appended. The book is of value not only to sanitarians and teachers, but to physicians as well. The latter will appreciate it as a reference book, more particularly because of the chapters which treat of insects that are directly poisonous or injurious to man. The authors note what is considered the best treatment of the different insect bites, stings or poisoning by nettling larvæ, but do not tell of anything of especial interest in this connection. The illustrations borrowed from medical works are in some instances poorly chosen because they are of too extreme and unusual cases. This applies particularly to those of pediculosis. In telling of the measures for getting rid of bedbugs the authors omitted one of the best and most easily practicable, namely, the use of a mixture of bichloride of mercury, alcohol, and turpentine. This solution is painted about the infested places; the bichloride remains finely emulsified in a thin layer of turpentine after the alcohol evaporates; when the bug comes out and crosses this painted zone she gets some of the sticky turpentine on her legs and in licking it off becomes poisoned with the bichloride. The book contains synoptic tables of the hominoxious arthropods and this is of value for reference in looking up the correct zoological nomenclature. The authors could have enhanced the value of the book as a reference work by giving the synonymy. The reader is called upon to make as many as thirty important corrections from a slip pasted in the front of the book. Altogether, in spite of certain imperfections in the work, the authors are to be commended for having compiled a valuable reference book.

Medical Applied Anatomy for Students and Practitioners. By T. B. Johnston, M.B., Ch.B., Lecturer on Anatomy, University College, London; lately Lecturer on Anatomy, Edinburgh University, and Lecturer on Medical Applied Anatomy Edinburgh Post-Graduate Courses in Medicine and Surgery. Containing three full-page plates in color and 146 other illustrations in the text. London: A. and C. Black, Limited; 1915.

This book marks a new departure in text books on Anatomy. It is intended to present to the physician the main anatomical facts which will help him in the study or practice of Clinical Medicine, and the volume is thus analogous to several well known useful works on Applied Surgical Anatomy. In the present work the subject has been treated according to Systems and not according to Regions. The reader will not be surprised to find that the nervous system occupies about one-half the volume; the other chapters deal with the organs of special sense, the digestive system, the vascular system, the respiratory system, the genito-urinary system, and the ductless glands. The volume is well written and cannot fail to be of service to the physician who finds his knowledge of Anatomy becoming a little dull.

Blood Pressure in General Practice. By Percival Nicholson, M.D. With eight Illustrations. Third Edition. Philadelphia and London: J. B. Lippincott Company, 1915.

This book was written with the view of affording to the general practitioner and surgeon all needful information regarding blood pressure entirely from the standpoint of its practical significance and value. As Dr. Nicholson points out in the introduction, while the whole subject of blood pressure is recent the literature published thereon, mainly in journals and magazine articles, is so extensive that the busy practitioner has no time to wade through the mass and to winnow the wheat from the chaff. It was with the object, therefore, of presenting the matter of blood pressure from a practical standpoint in a concise and easily intelligible form that the book under review was written. The author has succeeded in his aim admirably and his treatise should prove highly useful to the readers for whom it is intended.

A Textbook of Histology. By Rudolf Krause, A. O. Professor of Anatomy at the University of Berlin. Translated from an original manuscript and printed only in the English language. With thirty-six illustrations in the text, three of which are colored. The references to illustrations given in the text relate to the colored illustrations contained and published in Dr. Rudolf Krause's "A Course in Normal Histology." Price, $2.50. New York: Rebman Company, 1915.

This small volume of 274 pages is apparently intended as a student textbook of histology to be used in laboratory instruction and to be supplemented either by wall charts or by the use of the author's well known "Course in Normal Histology," which is illustrated by a large series of admirable colored plates. It can not, therefore, be considered as a general reference work for histology, but as a student text merely it fulfills its purpose very well. The arrangement, printing, and illustrations are very satisfactory, and the textual presentation of the rudiments of histology is clear and adequate.

Society Reports.

AMERICAN ASSOCIATION FOR THE STUDY AND PREVENTION OF INFANT MORTALITY.

Sixth Annual Meeting, Held at Philadelphia, Nov. 10-12, 1915.

DR. CHARLES A. FIFE OF PHILADELPHIA, IN THE CHAIR.

The Statistical Study of Respiratory Diseases as a Factor in the Causation of Infant Mortality.—Dr. WILLIAM C. WOODWARD of Washington, D. C., from this study believed that the importance of diseases of the respiratory system as a causative factor in deaths in the first year of life was not appreciated. The degree of prevention of such deaths by the present known methods he said was yet to be determined. Since much prophylactic work had been done in diseases of nutrition, including diseases of the digestive tract, through "infant consultations," for the prevention of still births and deaths due to complications of labor and diseases incident thereto through the same agency and through prenatal nursing, the next step toward lowering of infant mortality he felt should be in the direction of establishing machinery and the adopting of at least tentative methods for the prevention of respiratory diseases. He called attention to the fact that in the registration area of the United States in the calendar year 1913 that 15.85 per cent. of the total mortality in the first year of life was due to diseases of the respiratory system. This was approximately one-quarter of the total mortality from these diseases at all age periods taken together. Therefore, one-quarter of the total mortality from diseases of the respiratory system came within the purview of the conservation of infant welfare. Bronchitis and pneumonia were said to cause 95 per cent. of all deaths in the first year of life from diseases of the respiratory system. The prevention of infant mortality from diseases of the respiratory system obviously claimed the work of the prenatal nurse, the obstetrician, the midwife, the pediatrician and the infant welfare station.

The Prevention of Respiratory Diseases.—Dr. ROYAL STORRS HAYNES of New York City recognized two important factors in the prevention of respiratory diseases: (1) Destruction or exclusion of the infecting organism; (2) Preservation of the resistance. Transference by contact which was said to be the method of infection in most instances he said could be avoided by real cleanliness. In the preservation of the resistance the maintenance of a perfectly functioning vasomotor system was said to be of the greatest importance. In the prevention of respiratory diseases the author suggested the appointment of a committee whose duties might be (*a*) Supervision of the conduct of an intensive investigation of respiratory affections in a selected area in a selected city. By such an investigation it should be possible to determine the relative etiological importance of various factors and the value of prophylactic measures. The investigation should embrace the work of social workers, physicians, physiologists, sanitary engineers and bacteriologists. (*b*) To arrange for publication through the medical and lay press of articles acquainting the laity with the economic loss and that of health and life caused by these diseases. (*c*) To investigate the various State laws upon health and improve legislation where desirable. (*d*) To carry on an education campaign by lectures for those not reached by the printed page. (*e*) To stimulate the care of the child before the school age by placing greater emphasis upon his medical supervision between the nurses and social workers regarding this question.

The Treatment of Respiratory Diseases, with Special Reference to the Value of Fresh Air.—Dr. JOHN LOVETT MORSE of Boston said that great confusion prevailed in connection with the use of the term, "fresh air," Such air might be defined as air which was in motion, dry, and cool. It was not necessarily outdoor air. Fresh air and cold air were not identical. In certain diseases of the respiratory tract cold air, it was said, was an irritant to the respiratory mucous membrane. Because of its stimulating effect upon the vasomotor system it had been thought to be of advantage in the treatment of pneumonia. Recent investigations had shown that blood pressure was not lowered in pneumonia, nor the vasomotor system impaired. Fresh air was claimed to be of advantage in all diseases of the respiratory tract. Cold air did harm in acute stages of nasopharyngitis, laryngitis and in bronchitis; while it might, or might not be of advantage in the later stages of these conditions and in bronchopneumonia. Dr. Morse believed it questionable whether or not cold air lowered mortality in pneumonia. Discrimination in the use of cold air in the treatment of diseases of the respiratory system was to be observed since all such diseases were not amenable to the same methods.

Dr. L. EMMETT HOLT of New York City strongly emphasized the importance of quarantining the infant, especially the premature infant, when other members of the family had colds, and pointed out that efforts against the contagiousness of pneumonia should be directed to raising the resistance of the infant. He believed that almost as many deaths had been caused by cold air as there had been cures effected and agreed with Dr. Morse that great discrimination should be observed in its application. Especially in young infants he had seen much harm done in the treatment of acute respiratory diseases by exposure to cold air.

Dr. S. MCC. HAMILL of Philadelphia recognized the value of the foundation for the fight against infant mortality given in the papers. He ventured a word of caution in the use of vaccines in the prevention of colds, feeling that the whole question of vaccine therapy was at the present time so unsettled and its dangers so manifest that the subject should never be presented without a word of caution against its promiscuous use. The use of the nasal douche in the prevention of the common cold he thought also called for a word of caution because in the final analysis this method was apt to do more harm than good. He was in entire sympathy with Dr. Morse in his belief that fresh or cold air had been incautiously employed. In pointing out that in the treatment of all conditions the individual and not a group of cases should be treated, he felt that Dr. Morse had covered the subject. He believed that the proper way to obtain "cool, dry, and moving" air, defined by Dr. Morse as fresh air, was through the open windows, and not by a ventilating system.

Dr. J. P. CROZER GRIFFITH of Philadelphia said it had never been proven to his mind that the universal employment of cold, fresh or open air, for the treatment of pneumonia or other respiratory diseases was the correct measure. When a number of years ago he had ventured to make this statement he had stood without any support, and he was glad to note the present changed sentiment. In explanation of such change of sentiment he said that a human failing was that of the following of fads; the excessive use of cold air for the treatment of respiratory diseases had been a fad and as such had gone beyond the medical profession into the hands of nurses, hospital managers and the laity in general. If among medical men there was doubt concerning cases in which this treatment was indicated, obviously the measure was not safe in other hands. Dr. Griffith advocated fresh air in the treatment of many diseases of the respiratory system but emphasized the need of great judgment in its use. He agreed with Dr. Holt that many cases were made worse by its indiscriminate use, while others improved only by this treatment.

Dr. CRESSY L. WILBUR said that the foundation of the work of the prevention of infant mortality was the registration of births and deaths. He thought it a shame to the country that such registration was not made. The only exception to this lack was in the State of Pennsylvania, the people of which commonwealth he thought should be congratulated upon having compelled such legislation.

Dr. GODFREY ROGER PISEK of New York City felt that fresh air and exposure to cold air should be differentiated that there might be no confusion in the minds of nurses and social workers regarding this question.

Dr. EMERSON of New York said that respiratory diseases incident to the epidemic of measles that had swept over that city during the present year would give a higher infant mortality than there had been at any previous time. That the death rate in hospitals had been larger than in homes in which the babies had been cared for by the visiting nurse and physicians was due to the fact of the great number of children necessarily sent to the hospitals because of mothers working away from the home. The rule had been established that children of this age were not to be referred to the hospitals unless this was made necessary by the home conditions. The influence of prenatal care upon the resistance of the young child was a matter to be emphasized.

Dr. HOOVER of New York thought it possible to classify by observation the two groups of cases spoken of in the discussion, comprising those who did well under outdoor treatment and those who did not. A child whose hands and feet were cold and who was uncomfortable when out of doors, regardless of the amount of clothing it wore, would obviously do better in the ward. Likewise a child, perfectly comfortable and breathing well in the ward, which became dyspneic when taken into the cold air, should be returned to the ward.

Dr. ABRAHAM JACOBI of New York City said that much he had heard in the discussion convinced him that some sixty years ago he had not been so stupid as twenty-five or thirty years later he had taken himself to be. At the former time he had been of the opinion that to speak of the treatment of "pneumonia" was a misnomer; the several peumonias being not the one and the same thing. In speaking upon this subject it was his custom to tell his students that they had in this disease a patient to deal with rather than a pneumonia. Unless every case were studied individually the best results could not be obtained. The aim of teachers should be to make good doctors of their students. The principal thing in diagnosis—and in the head of the doctor—was brains. So long as the doctor was not able to impress his nurses with the fact that he was their superior in knowledge, that he knew what he was about in a given case, the nurses would be his superiors in the management of the case, and he would be in the peculiar position of being run by the nurses and the hospital managers.

Dr. WOODWARD confessed to disappointment in its trend which had been that of curing pneumonia rather than of its prevention and the prevention of diseases of the respiratory system. Such prevention he felt to be summed up in the matters of clothing, housing, exercise, and personal cleanliness. When the Association could present these four factors to those responsible for the care of babies and children a reduction in diseases of the respiratory system might be hoped for.

Dr. HAYNES recalled the case of a nursing infant who had not taken whooping cough from the mother who had the disease; in another case care and cleanliness had prevented infection of the baby when every other member of the family had whooping cough. Both cases emphasized Dr. Holt's remarks upon precaution against infection of the nursing child. In deciding which ill children should be subjected to treatment by cold air their passivity should be carefully considered. The dryness of air mentioned by Dr. Morse it was thought should be qualified, and he was in accord with Dr. Hamill regarding treatment by the vaccines and postnasal douching. He had not in his paper recommended these methods of treatment, but had simply stated that they were employed.

Dr. MORSE admitted the difficulty of the differentiation of cold air and cool air. It might be said, however, that air of a temperature of fifty was cold air; above that cool. He wondered whether the gentlemen who had spoken upon quarantining the baby had realized what a hole they were getting the doctors into; with the isolation of the infant from the children coming from school, the dismissal of the nurse with a cold, logically, the doctor when he had a cold would have to give up his practice, and his income. In connection with what had been said by dressing the children in the morning by the thermometer rather than by the calendar it had been forgotten that in Boston it was not possible to know in the morning what kind of clothing would be needed in the evening. In the question of fresh, pure and cold air, he believed that a child should have fresh pure air. There remained, therefore, only the question of temperature, and this, obviously should be regulated according to the disease and the individual patient.

The Education, Licensing, and Supervison of the Midwife.—Dr. J. CLIFTON EDGAR of New York City said that the midwife, for traditional, social and economic reasons, attended about 40 per cent. of confinements in this country and was at the present time a necessary evil. The solution of the question in the rural districts was the inclusion of midwifery service should a physician not be available. In illustration of this the proposed course of midwifery in the Washington University Hospital in St. Louis was mentioned. The only legitimate functions of the midwife, Dr. Edgar said, were those of a nurse plus the attendance upon a normal delivery, when necessary, and she should never be regarded as a practitioner. Unlicensed women should not be permitted to practice, and even as a temporary measure only properly qualified women should be granted a license. He advocated the supervision of licensed midwives by the local department of health, as held in Buffalo, Pittsburgh and Providence, which system followed closely that operative in England and New Zealand, in which countries infant mortality was conspicuously low. A recent study of the midwife question in England, made by Miss Carolyn V. VanBlarcom, secretary of the New York Committee for the Prevention of Blindness, it was said had been used as a basis for midwife control in this country.

Is the Midwife a Necessity? — Dr. J. M. BALDY of Philadelphia under this caption said that this country contained several groups of foreigners who had been accustomed to the midwife, and that until immigration ceased and these people became evolved into Americans the midwife would be demanded. The question revolved itself into the proper education and control of the midwife. Results were to be obtained by meeting, and improving existing conditions. There was no State, city or town in the United States, he declared, in which by the passage of laws it had been possible to eliminate the midwife. Any measureable degree of success attained had come only through education and control.

Progress Toward Ideal Obstetrics.—Dr. JOSEPH B. DELEE of Chicago asserted his opposition to every movement to perpetuate the midwife, declaring her to be a relic of barbarism and that her continuance demanded a compromise between right and wrong. He regarded her as a drag upon the progress of the science and art of obstetrics, her existence stunting the one and degrading the other. He believed that the foreigner was becoming enlightened upon the value of medical attendance and demanding it. The visiting nurse, he said, did an amount of maternity and prenatal work not fully recognized. He believed there were thousands of young physicians who would take cases now cared for by midwives, were it not considered undignified work, and also undignified to accept such small fees for the service as were received by these women. In educating the midwife he felt that the profession assumed the responsibility for her, lowered the standards and compromised with wrong, and personally he refused to be *particeps criminis*.

Dr. WILLIAM R. NICHOLSON of Philadelphia believed that without inspection of every case of labor the midwife could not be controlled. He said that in Philadelphia five inspectors, graduates in medicine, inspected every case after delivery. He believed that the Ascosiation could do a larger amount of good if all its members worked upon a common ground. There appeared to be a division of opinion—for and against the midwife. To Dr. Nicholson the question at issue was the benefit of the women now attended by the midwife. He did not believe that the midwife could be eliminated at the present time; all they were doing in Philadelphia was carrying out a *police* supervision—there was no other word for it; the women being brought to account for any infraction of requirements, and this work was regarded only as a temporary expedient. Dr. Nicholson favored the training of a certain number of English speaking, intelligent young women to care as nurses for women in labor, believing that in this way the places of a number of midwives could be taken. Nine women were at the present time in such training. Dr. Baldy had given permission for the experiment and it was believed that the results would be satisfactory.

Dr. J. WHITRIDGE WILLIAMS of Baltimore believed that in the big cities, unless the man at the head of the inspection of midwives were a man like Dr. Baldy in forcefulness, failure would result. The development of prenatal work he believed one of the greatest advantages in modern obstetrics. Further development was in the oversight of the woman after confinement. The pre and postnatal work he said involved the work of the obstetrician, the pediatrist and the social worker. The crux of the matter lay in the education of doctors to be competent obstetricians. It was just commencing to be understood in this country what the obstetrician was. It was much more than a "man midwife." The inventor of the obstetrical forceps, Hugh Chamberlen, called himself, "Hugh Chamberlen, man midwife." "Man midwife" and "accoucheur" Dr. Williams declared were two terms that raised his ire. The "man midwife" had disappeared, and the "accoucheur" was disappearing. That which was wanted was the scientific obstetrician. Such a person could be obtained only by the development of medical education. There was needed a large, thoroughly equipped woman's hospital, where

everything pertaining to woman and child-bearing was studied from the viewpoint of teaching that which was now known, and for the acquisition of new knowledge for the future. Such a hospital lately endowed in Pittsburgh should set the pace for other cities.

Dr. S. Josephine Baker of New York City thought the discussion which had been held for the last five years was just as near solution as it had ever been, and this was because of failure to get together upon fundamental principles of the whole proposition. Dr. Baker's interest in the midwife was solely to make her as nearly fit as possible to give to mothers and babies their essential care. She believed it an absolute impossibility to abolish her in the city at the present time. The situation in New York City had been misinterpreted, and she assumed that Dr. DeLee, in speaking of the high mortality and morbidity following the work of the midwife was expressing his personal opinion. The statistics of New York City did not bear out this opinion. In proportion this mortality and morbidity was less than among the women attended by physicians. In the interim of securing the better education of the medical student Dr. Baker said the effort was being made to do that which seemed to be the most efficacious in protecting the mother and babe, and asked if those who would eliminate the midwife had anything better to offer. That which was needed was a practical, working program, better than the one in operation at the present time. The midwife was being eliminated and the complete elimination she believed would come by making the standard so high that the ignorant and untrained women could not attain it. Since at the present time the women would practice, licensed or unlicensed, she thought it infinitely better to see that the care given by them to mothers and babies was at least proper. Her experience was that in prenatal work the midwives gave efficient cooperation in referring mothers for instruction. Contrary to what had been said, the women did engage the midwife as early as women engage the doctor. Altogether the midwives in New York were beginning to look upon the health department, not as a body to be feared, but as something which was a very definite help to them. By such cooperation Dr. Baker believed more effective reforms would be secured than by radical measures.

Dr. Arthur B. Emmons of Boston said that in Massachusetts nothing was being done specifically to eliminate the midwife; their law required the registration of physicians, and if a midwife wanted to qualify before the Board of Licensure she must pass the examination. The daughter of one midwife had already taken a course in medicine and qualified as a physician. This plan operative in Boston he believed solved the question of the elimination of the midwife. He referred also to a plan of prenatal clinics and conference which had been worked out in that city. From the graduates of the lying-in hospital a number of young physicians attended the women, receiving from five to ten dollars, depending upon the section of the city in which the patients lived. The follow-up work was done by the visiting nurses and the results had been quite satisfactory. He felt that Pennsylvania led in the requirements for medical licensure.

Dr. Abraham Jacobi of New York City said he was interested only in the poor woman of the people. In the last report of the Lying-in Asylum of New York it was stated that 6,000 women had been cared for by the Asylum in their homes and in the institution. From other sources he had read that 52,997 women had been confined in their homes by midwives. That, he felt, told the whole story—53,000 in New York, and more than a million in the United States, who must have midwives. If the midwife were to be eliminated, then the women whom they had attended must be provided with just such service as they wanted and could afford to pay for. Dr. Jacobi said he knew well what he was talking about, for he had been a "midwife" himself fifty or sixty years ago—and at a five or ten dollar fee. He questioned whether his audience knew what a midwife was at that time; he attended the woman through her confinement and washed the baby. He washed the baby the next day and for eight or nine days—nine days was the usual time. He did not know whether his hearers had heard of those antedeluvian times.

Dr. George W. Kosmak of New York City differed with Dr. Baker in her belief that the problem of the midwife was no nearer solution than when the discussion was new. Advance had been made in that those who had favored the midwife now admitted that she must be eliminated. For this elimination he thought there was no stronger argument than that she should be under supervision.

Dr. Williams said that in the rural districts there was no demand for obstetric hospital and dispensaries, but that there was a demand for good midwives. If the midwife were not available the farmer's wife could get only the neighboring farmer's wife to look after her in confinement. He expected to see for some time the midwife in the State of New York, and it was his intention that there should be established some such supervision as that developed by Dr. Baldy in Pennsylvania.

Election of Officers.—*President*, Dr. S. McC. Hamill, Philadelphia; *President-elect* (1917), Dr. W. C. Woodward, Washington; *First Vice-President*, Dr. Joseph S. Neff, Philadelphia; *Second Vice-President*, Dr. Thomas McCleave, Berkeley; *Secretary*, Dr. Philip VanIngen, New York; *Treasurer*, Mr. Austin McLanahan, Baltimore; *Executive Secretary*, Miss Gertrude B. Knipp, Baltimore. Place of next meeting, Milwaukee.

(To be continued)

Books Received.

The Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Practical Cystoscopy. By Paul M. Pilcher, M.D. Second edition, thoroughly revised and enlarged. Octavo of 504 pages, with 299 illustrations, 29 in colors. Published by W. B. Saunders Company, London and Philadelphia. Price, cloth, $6.00 net; half Morocco, $7.50.

The Medical Clinics of Chicago, November, 1915. Vol. I, No. 3. Octavo of 200 pages; 23 illustrations. Published by W. B. Saunders Company, London and Philadelphia. Price per year, paper, $8.00; cloth, $12.

Post-Mortem Examinations. By William S. Wadsworth, M.D. Octavo volume of 598 pages with 304 original illustrations. Published by W. B. Saunders Company, Philadelphia and London. Price, cloth, $6.00 net; half morocco, $7.50 net.

The American Illustrated Medical Dictionary. Edited by W. A. Newman Dorland, M.D. Published by W. B. Saunders Company, Philadelphia and London. Eighth Revised Edition. Large octavo of 1135 pages, with 331 illustrations, 119 in colors. Price, flexible leather, $4.50 net; thumb index, $5.00 net.

Bone-Graft Surgery. By Fred. H. Albee, M.D. Octavo volume of 417 pages, with 332 illustrations, three of them in colors. Published by W. B. Saunders Company, Philadelphia and London. Price, cloth, $6.00 net; half Morocco, $7.50 net.

Medical and Veterinary Entomology. By William B. Herms. Published by The Macmillan Company, New York. Illustrated; 393 pages. Price, $4.00.

American Sewerage Practice. By Leonard Metcalf and Harrison P. Eddy. Published by McGraw-Hill Book Company, Inc., 239 West Thirty-ninth Street, New York. Vol. III, 851 pages. Price, $6.00 net.

Colon Hygiene. By J. H. Kellogg. Published by Good Health Publishing Company, Battle Creek, Mich.; 393 pages.

Medical and Surgical Report of the Roosevelt Hospital, New York; 254 pages. Edited by Frederick T. Van Beuren, Jr., M.D.

Report of Births, Marriages and Deaths in the Province of Ontario, for the year ending December 31, 1914, being the Forty-fifth Annual Report. Printed and published by L. K. Cameron, printer to the King's Most Excellent Majesty; 285 pages.

The Rockefeller Foundation. Annual Report, 1913-1914. Second Edition. The Rockefeller Foundation; 226 pages.

Selbstmordverdacht und Selbstmordverhütung. Von Dr. Paczek, Nervenarzt in Berlin. Published by Georg Thieme. Leipzig, 1915; 272 pages. Price, 6 marks.

Bandaging. By A. D. Whiting, M.D. Published by W. B. Saunders Company, Philadelphia and London. 12mo, of 151 pages, with 117 original illustrations. Price, cloth, $1.25 net.

INDEX.

A

Abbe, R., lymphangioma and radium, 215.
Abdernalden reaction, alleged fallacy of, 110; and defective mental and physical states, 172; and syphilis, 43o; in pregnancy, 544; modification of the, 710.
Abdomen, contraindications to use of oil in, 66; submuction from foci in, 412; treatment of injuries of, in the field, 714; wounds of, 74.
Abdominal wall, torsion injuries of, 1092.
Abortion, 710; epidemic, reactions of, among children, 37; meaning of, in insurance policy, 1023; treatment of, 765.
Abscess, dental, blind, 209; parapharyngeal, 462; tuberculous, of brain, and dementia, 737.
Abstainers and drinkers, relative death rates of, 456; and non-abstainers from alcohol, comparative mortality experience among, 732.
Acanthosis nigricans and internal malignancy, 535.
Acarus, the artful, 972.
Accident insurance, 977; evidence of cause of death in, 31; legal decisions in, 206.
Account books, authentication of, 1094.
Acetonuria and carbohydrate starvation, 452.
Achalasia of the cardia, 788.
Acid-fast bacilli in feces, significance of, in joint disease, 865; resistance of, to antiformin, 877.
Acid intoxication in hyperemesis of pregnancy, 755; picric, poisoning, and icterus, 704.
Acidosis, 487; in diabetes mellitus, 622.
Aconites, action of, 868.
Acrocephalosyndactylia, 256.
Acromegaly, impairment and loss of sexual power in, 829.
Actinomycosis, acute, of parotid gland, 799.
Adaptations, enzymatic, 406.
Adenitis, chronic, cervical, and tonsils 757.
Age, old, and longevity, 157.
Agglutination reactions after anti-typhoid inoculation, 579.
Air, hot, dry, for disinfection, 1095; therapy, in gynecology, 537.
Air-ways, acute infections of, successful treatment for, 883.
Albee, F. H., the bone graft wedge in the treatment of habitual dislocation of the patella, 257.
Albumin from the air, 496.
Albuminuria, Bence Jones, and lymphatic leucemia, 1013.
Alcohol, abstainers and non-abstainers, comparative mortality among, 456, 732; craving for, 944; peace and war footing of, 226; psychopathies from, 1096; treatment of superficial burns, 382.
Alcoholism, 242; in France, 750.
Aleukia hemorrhagica, 799.
Alimentary canal, stasis in, 155; the fluoroscopic screen and the radiographic plate in the diagnosis of medical and surgical lesions of, 639.
Allergy, see idiosyncrasy.
American ambulance, report of Harvard University at the, 932.
Amnesia, verbal, and alexia, 944.
Amputation by plane circular section, 798.
Anaerobe sepsis, 975.
Analgesia in intranasal surgery, 159; obstetrical, a method of, 214.
Anaphylaxis, food, 483.
Anderson, J. H., chemical and pathological observations in a case of mercury poisoning, 357.
Anderson, T. McC., neuritis, the modern American disease, 518.
Andrews, V. L., chemical and pathological observations in a case of mercury poisoning, 357.
Anemia, pernicious, splenectomy in, 202.
Anesthesia, 796; by rectum in thyroidectomy, 933; caudal, for prostatectomy, 891; closed ether, and a color sign, 118; for suprapubic prostatectomy, 887; intratracheal ether, in surgery of brain and spinal cord, 494; nitrous oxide, at Lakeside, 1065; rectal, in thyroidectomy, 763.
Anesthetics and coagulation time of blood, 226.
Anesthetist, liability of, 403.
Aneurysm, 74; partial occlusion in treatment of, 459; unusual, 584.
Angina pectoris, 131; and Raynaud's disease, 415; explanation of sudden death in, 1107.
Anociassociation in medical practice, 370; in obstetrics, 251.
Anorectal affections, simplified treatment of, 595.
Anthrax, case of, 982.
Antiformin, resistance of acid-fast bacilli to, 877.
Antiseptic, hypochlorites as, 367; malachite green as, 367; mixture, a new, 286; nontoxic, 1103; paste, 663.
Antitoxin, diphtheria, intramuscular injections of, 803; diphtheria, intravenous injection of, 703.
Aorta, dilatations of, 810.
Aortitis, malignant, 369.
Aphasia, transient, due to arterial spasm, 846.
Aphonia, functional, 848.
Apoplexy, surgical measures in, 158.
Appendectomy, a single stitch, 517.
Appendicitis, acute, late results in, 766; acute, unusual complication of, 843; as complication of pulmonary tuberculosis, 589; chronic, in relation to cardio- and other neuro-spasm, 355; disease of liver associated with, 411; pathology of, 249; pylephlebitis complicating, 151; suppurative, fecal fistula in, 765; transverse incision in, 40, 535; tuberculous ileocolic glands simulating, 451.
Appendix, fibroid degeneration of, 251; pseudomucinous cyst of, 897; surgery of, 675.
Arch supporters for fallen arches, 149.
Army, infectious diseases in, 1022.
Arryhthmia, unusual type of cardiac, 710.
Arsenicals, lesions produced by, 1011.
Arterial tension in connection with cardiac murmurs, 822.
Arteries, coronary, and heart stimulants, 415; functional diseases of, 444; internal carotid, sigmoid tortuosity of, 244; pressure in, see blood pressure; right-sided hypertension of, postoperative, 536.
Arteriosclerosis, 238; and control of uterine hemorrhage, 86; as cellular disease, 1064; as seen by the ophthalmoscope, 85; cardiovascular-renal disease, 593; cerebral, psychoses associated with, 1003; epistaxis in, 86; importance of early recognition of, 854; in relation to life insurance, 87; in relation to ophthalmology, neurology, and surgery, 85; of uterine vessels, 850; pupil in, 202; surgery in, 85; with relation to prostatic operations, 86.
Arthritis, chronic, 806, deforming, advance in treatment of, 809; hypertrophic, late results of operations for, 883; pneumococcic, 534; suppurative, in cerebrospinal meningitis, 78; syphilitic, 472.
Arthroplasty, bone grafting and, 775.
Ascites, treatment of, 298; treatment, surgical, of, 764.
Aspergillosis, pulmonary, case of primary, 587.
Asthma, autogenous vaccines in, 891; bronchial, nature and treatment of, 76; horse, treatment of, by normal horse serum, 843; a pituitary extract in, 454.
Ataxia, acute cerebellar, in children, 540; congenital cerebellar, 256.
Athlete, heart of, 804.
Auricular fibrillation, prognosis of, 28; flutter accompanying acute endopericarditis, 995.
Autoinoculation, in the treatment of mouth infections, 179, 207.
Autolysm, 886; cancer treated with, 933; treatment of cancer, 666, 709.
Autolysis, products of, and influence on tumor growths, 233.
Automatic balances in the human body, 948.
Automobile and its driver, 237.
Autopsy as evidence, 109; war, and tuberculosis, 749.
Autoserotherapy, 406; technique of, 108.
Ayres, W., the effect of intravenous injections of radium on a persistent positive Wassermann reaction, 610.

B

Babies, premium on, 902.
Bacilli, acid-fast, in feces, significance of, in joint disease, 864; acid-fast resistance of, to antiformin, 877; dysentery, of the toxin-poor type, 712.
Bacillus tuberculosis in circulating blood, 814; typhosus, viability of, in ice cream, 973.
Backache, 667, 709; gynecological aspects, 577.
Bacteria, antagonism of, 1066; of trees and men, 89.
Bailey, C. H., complement fixation in chicken sarcoma, 403.
Baird, A. W., a health week in the public schools, 481.
Balances, automatic, in the human body, 948.
Baldness, causes of, 262; predestined, 1108.
Bancroft, F. W., section of the posterior roots of the sixth to the tenth thoracic nerves for the relief of severe gastric crises in locomotor ataxia, 696.
Bandler, S. W., observations on the use of pituitary extract, 607.
Banti's symptom complex, 458.
Beard, J., the menace of cancer, 325.
Beck, Joseph C., a case of combined extracranial paralysis of cerebral nerves, 308.
Bence-Jones albumin, diagnostic value in the early stages of a case of multiple myeloma, 600; albuminuria and lymphatic leucemia, 1013.
Benzidin and picric acid stain, 787.
Benzol, poisoning, acute, chemical diagnosis of, 1108.
Besredka's vaccine, treatment of typhoid fever with, 580.
Best, W. H., a frequently unrecognized symptom-complex, 315.
Biggs, H. M., Milk-borne septic sore throat—a new health problem, 945.
Bile, bedside study of, 43; feeding in patients with biliary fistulæ, 590.

Biliary tract, disease of, operative results in, 459.
Binet-Simon, method in adult prisoners, 244; tests, broadening scope of, 444.
Bishop, L. F., cardiovascular-renal disease (arteriosclerosis), 593.
Blackwater fever, 1067.
Bladder and uterus, prolapse of, 895; function after parturition, 421; papilloma, fulguration treatment of, 764; papilloma of, high frequency treatment, limitations of, 841; tumors in young, 1102.
Bleeding for madness, 660.
Blindness, occupations for soldiers afflicted with, 288; total color, 704.
Blood and plasma volume, determination of, 789; animal, as food, 204, 878; circulating, tubercle bacilli in, 207; coagulation time of, and anesthetics, 226; counts, differential, in 662 young men, 708; counts in relation to vaccine therapy, 179, 207; cryoscopy and blood urea, 973; examination of, practical deductions from, 855; ferments in nephritis, 613; leucocytes, immature, in, in infectious disease, 1068; of children, total non-nitrogen and urea of, 502; platelets and megacaryocytes, 391; platelets, origin of, 976; portal, proteolytic ferments in, 331; pressure, 619; pressure, and neosalvarsan, 453; pressure, diastolic, 242, 493, 1033; pressure, effect of athletic training on, 670; pressure, high, hemoptysis, due to, 412; pressure, high, muscular relaxation in treatment of, 620; pressure in dysthyroidism, 584; pressure in life insurance examinations, 538; pressure in spinal anesthesia, 666; pressure readings in life insurance examinations, 416; pressure, urinary findings and differential blood counts in 662 young men, 708; reaction of, and dyspnea, 236; serum, refractometric determinations, 797; sugar in, 111; sugar, influence of muscle work on, 937; stains on accused's clothing, 150; transfusion, 425; transfusion, dangers of, 1096; transfusion, direct, use of sodium citrate for, 676; transfusion, indirect, by sodium citrate method, 757; tubercle bacilli in, 814; urea in renal conditions, 620; vessels, surgery of, 74; viscosity of, 528.
Boards of Health, teaching functions of, 660.
Boeck's sarcoid with participation of internal organs, 937.
Boehme, G. F., torsion injuries of muscles of abdominal wall, 1092.
Bond, S., a disclaimer, 931.
Bone, graft wedge, 451; grafting and arthoplasty, 775; grafts, autogenous versus Lane plates, 486; injuries to, at tendon and ligament insertions, 795.
Bonnot, Edmond, quinine after rectal operations, 786.
Book Reviews:
Alligator, the, and its allies, by A. M. Ries, 457.
American Pediatric Society, transactions of, edited by L. E. La Fétra, 1024.
Anatomy, applied, for students and practitioners, by T. B. Johnston, 1109.
Anatomy, Quain's elements of, edited by Sir E. A. Schäfer, J. Symington, and T. H. Bryce; Vol. IV, Part 1, osteology and arthrology, by T. H. Bryce, 374.
Arteries, disease of the, including angina pectoris, by Sir Clifford Allbutt, 582.
Babies, fewer and better, by William J. Robinson, 761.
Bacteriology, the principles of, by A. C. Abbott, 498.
Billings, John Shaw, a memoir by F. H. Garrison, 457.
Blood pressure in general practice, by Percival Nicholson, 1109.
Bronchi, lungs, and pleura, diseases of the, by F. T. Lord, 122.
Cancer, its study and prevention, by H. C. Taylor, 978.
Cane, the gold-headed, by W. Carmichael, with an introduction by Sir William Osler and a preface by F. R. Packard, 374.
Cane sugar and heart disease, by Arthur Goulston, 940.
Cerebrum, on the functions of, by S. I. Franz, 940.
Chemistry and toxicology, medical, a textbook of, by J. W. Holland, 248.
Childbirth, painless, by M. Tracy and M. Boyd, 457.
Chirurgie des Ohres und der oberen Luftwege, Handbuch der speciellen, von L. Katz, 717.
Chirurgische Operationslehre für Studierende und Aerzte, von Prof. Dr. F. P. Leusden, 761.
Circulation in health and disease, modern aspects of the, by C. J. Wiggers, 499.
Clinics, international, edited by H. W. Cattell, Vol. II, twenty-fifth series, 1915, 499.
Clinics of John B. Murphy, M.D., 290; 802.
Clinics, the medical, of Chicago, 539.
Cookery, meatless, by M. McI. Gilmore, with introduction by L. F. Bishop, 123.
Cystoscopy and urethroscopy for general practitioners, by B. Lewis and E. G. Mark, 625.
Deaf child, what the mother of a, ought to know, by J. D. Wright, 717.
Dental metallurgy, notes on, by B. Hepburn, 539.
Diabetes mellitus, by N. B. Foster, 163.
Diagnosis differential, Vol. II, by R. C. Cabot, 32.
Diagnosis, medical, by A. Latham and J. Torrens, 123.
Diet and disease in infancy, by H. Ch. Cameron, 716.
Differential diagnostische Tabellen der inneren Krankheiten, von J. Cemach, 1024.
Digestive organs, diseases of, by Charles D. Aaron, 761.
Dreams, the meaning of, by I. H. Coriat; Mind and Health Series, edited by H. A. Bruce, 499.
Education, biography, travel, etc., selected addresses on, by J. Tyson, 163.
Electricity, Röntgen rays, and radium, medical, with a practical chapter on phototherapy, by S. Tousey, 248.
Embryology, a laboratory manual and textbook of, by C. W. Prentiss, 248.
Emotions, the origin and nature of the, by G. W. Crile, edited by A. F. Rowland, 498.
Encyclopedia of medical treatment, practitioner's, edited by W. L. Brown and J. H. Murphy, 978.
Endocrine glands and internal secretions, an introduction to the study of, Lane medical lectures, 1913, by Sir E. Schäfer, 582.
Entomology, medical, handbook of, by W. A. Riley and O. A. Johannsen, 1109.
Evolution and disease, by J. T. C. Nash, 625.
Exercise in education and medicine, by R. T. McKenzie, 1024.
Eye, Swanzy's handbook of diseases of the, and their treatment, edited by L. Werner, 539.
Factory, the modern: safety, sanitation, and welfare, by G. M. Price, 32.
Feldarztes, Taschenbuch des, von A. Dieudonné, 672.
Formulary, the new standard, by A. E. Hess and A. E. Ebert, 374.
Fractures, the operative treatment of, by Sir W. Arbuthnot Lane, 374.
Fractures, the treatment of, with notes on a few common dislocations, by Ch. L. Scudder, 625.
Gas poisoning in mining and other industries, by J. Glaister and D. D. Logan, 539.
Gastrointestinal tract, clinical anatomy of, by T. Wingate Todd, 761.
Gastrointestinal tract, diarrheal, inflammatory, obstructive, and parasitic diseases of, by S. G. Gant, 978.
Gynecology, operative, by H. S. Crossen, 499.
Gynecology, students' manual of, by J. O. Polak, 80.
Habits that handicap, by C. B. Towns, 890.
Hair, loss of, authorized translation from the German of F. Nagelschmidt, by R. W. Muller, 716.
Heart failure, the early diagnosis of, and other essays on the circulation, by J. S. Wilson, 499.
Heart, lectures on the, by T. Lewis, 123.
Histology, textbook of, by R. Krause, 1109.
Hospitals and charities, 1915, Burdett's, by Sir H. Burdett 163.
Hygiene, principles of, by D. H. Bergey, 122.
Hygiene, student's textbook of, by W. J. Wilson, 802.
Infant feeding, by F. L. Wachenheim, 123.
Infant feeding, simplified, by R. A. Dennett, 716.
Infants and young children, what every mother should know about her, by Ch. G. Kerley, 716.
Infection and immunity, a textbook of immunology and serology, for students and practitioners, by C. E. Simon, 290.
Infection, immunity and specific therapy, a practical textbook of, with special reference to immunologic technique, by J. A. Kolmer, with an introduction by A. J. Smith, 248.
Infektionskrankheiten und Immunitatsforschung, klinische Beitrage, von Prof. Dr. L. Brauer, etc., 761.
Insanity of youth and other essays, by Bayard Holmes, 761.
Internal medicine, outlines of, for the use of nurses, by C. B. Farr, 802.
International Clinics, edited by H. W. Cattell, 978.
Intestinal stasis, chronic, the operative treatment of, by Sir W. A. Lane, 625.
Karzinome, die Enstehung und Behandlung der, von A. Thielhaber, 80.
McNaughton, George, a biographic memorial of, 80.
Malay poisons and charm cures, by J. D. Gimlette, 279.
Materia medica and therapeutics, a textbook for nurses, by L. A. Parker, 498.
Materia medica, practical, and prescription writing, by O. W. Bethea, 890.
Mechanotherapeutics in general practice, by G. de Sivietchowski, 80.
Medical annual, the international, a year book of treatment and practitioner's index, 290.
Medical chemistry, compend of, by H. Leffmann, 1025.
Medical clinics of Chicago, Vol. I, No. 2 (September, 1915), 1109.
Medical ethnology, by C. E. Woodruff, 32.
Medical jurisprudence and toxicology, a textbook of, by J. Glaister, 672.
Medical Record visiting list, 1024.
Medical treatment, synopsis of, by G. S. Shattuck, 1109.
Medicine, a textbook of the practice of, by H. A. Hare, 80.
Medicine, modern, its theory and practice, edited by Sir William Osler and T. McCrae; Vol. V, diseases of the nervous system, diseases of the locomotor system, 498.
Mental development, nature and nurture in, by F. W. Mott, 457.
Microbes and men, by R. T. Morris, 716.
Motives, human, by J. J. Putnam, 498.
Mothercraft, by S. Comstock, 716.
Narcotic law, Federal, a reference book on the, by A. D. Currier and D. R. Forbes, 122.
Narcotic record book, Federal, 162.
Nervous and the insane, nursing and care of the, by C. K. Mills, revised by the author, assisted by N. S. Yawger, 417.
Nervous diseases, textbook on, edited by C. W. Burr, 1024.
Nervous system, diseases of the, by S. E. Jelliffe and W. A. White, 890.
Nose and throat, a textbook of diseases of the, by D. Braden Kyle, 248.
Obstetrical nursing, by C. S. Bacon, 122.
Obstetrics, principles and practice of, by Joseph B. De Lee, 1025.
Occupational affections of the skin, by R. P. White, 717.
Operationsfreihert, die, im Lichte fortschreitender Strafrechtsreform, von H. Lieske, 625.
Ophthalmic Year Book, edited by E. Jackson, 1025.
Ophthalmoscopic diagnosis for general practitioners and students, by G. W. Jean, 1109.
Overcrowding and defective housing in the rural districts, by H. B. Bashore, 672.
Parasiten des Menschen, die tierischen, bearbeitet, von M. Braun und O. Seifert; I Teil: Naturgeschichte der tierischen Parasiten des Menschen, von M. Braun, 290.
Pathologie, soziale, von A. Grotjahn, 499.
Personal hygiene, a manual of, by W. L. Pyle, 717.
Pharmacopœia, the extra, of Martindale and Westcott, revised by W. H. Martindale and W. W. Wescott, 374.
Pharmacopœias and unofficial formularies the book of, by E. W. Lucas and H. B. Stevens, 163.
Physical diagnosis, by Richard C. Cabot, 978.
Physicians' visiting list, 1024.
Physiology, human, principles of, by Ernest H. Starling, 940.
Physiology, the newer, in surgical and general practice, by A. R. Short, 123.
Popes and science, the. The history of the papal relation to science during the Middle Ages and down

to our own time, by J. J. Walsh, 582.
Praktikum der Chirurgie, von O. Nordmann, 890.
Prescriptions, the book of, by E. W. Lucas, with introduction by A. Latham, 123.
Prognosis, an index of, and end-results of treatment, edited by A. Rendle Short, 411.
Progressive Medicine, edited by H. A. Hare, 802, 1025.
Psychoanalysis, the theory of, by C. G. Jung, 411.
Pyelography (pyelo-ureterography), by W. F. Braasch, 539.
Pyorrhea, alveodental, by C. C. Bass, 582.
Radiography, *x*-ray therapeutics, and radium therapy, by R. Knox, 417.
Reference Handbook of the Medical Sciences, edited by T. L. Stedman, Vol. V, 122.
Rockefeller Institute for Medical Research, studies from, Vol. XXI, 940.
Royal College of Physicians, Edinburgh, report from laboratory of, edited by J. J. Graham Brown and J. Ritchie, 1024.
Salvarsantod, der, seine Ursache und seine Vermutung, von C. Schindler, 80.
Sanitary science, practical, a handbook for the public health laboratory, by D. Somerville, 80.
School children, health of, compiled by W. H. Heck, 940.
School hygiene, by Leo Burgerstein, 940.
Senescence and rejuvenescence, by Ch. M. Child, 672.
Seuchenentstehung und Seuchenbekämpfung, von F. Neufeld, 248.
Skin, diseases of, practical treatise on, by O. S. Ormsby, 802.
Skin, diseases of the, by J. H Sequeira, 32.
Surgery of the blood vessels, by J. S. Horsley, 802.
Surgical association, American, transactions of, Vol. XXXII, edited by A. MacLaren, 163.
Symptoms in medical practice, urgent, by R. Saundly, 582.
Syphilis und Nervensystem, von M. Nonne, 1025.
Therapeusis, modern biologic, from Lederle Antitoxin Laboratories, 1025.
Treatment, physiological principles in, by W. L. Brown, 32.
Tuberculin, a guide to the use of, by A. W. Cochrane and C. A. Sprawson, 890.
Tuberculosis, pulmonary, operative treatment of, and artificial pneumothorax, by F. Jessen, 940.
Urethritis beim Manne, die nichtgonorrhoische, von C. Adrian, 1025.
Urinary analysis and diagnosis by microscopical and chemical examination, by L. Heitzmann, 290.
Verwundeten im Felde, über die Versorgung unserer, von W. Körte, 374.
Warp and woof, by L. Pierce Clark, 1025.
X-rays, how to produce and interpret them, by H. Mowat, 716.
Bookman, M. R., a diagnostic sign in inflammatory conditions and traumatisms in and about the liver, 148.
Books, tuberculous infection retained in, 203.
Botulism, 43.
Boyd, W. A., impairment and loss of sexual power in acromegaly, 829.
Brain abscesses, tuberculous, and dementia, 737; carcinoma, metastatic of, 1046; congenital absence of cerebral hemispheres of, energy metabolism in, 463; cortex of, studies in decomplication of, 81; lipoid as a hemostatic, 579, 799; postnatal growth of, 168; telangiectasis within, 170; treatment of syphilis of, 621; tumor causing homonymous hemianopsia, 943, ventricle of, hemorrhage in, 169.
Branchial fistula in an adult, 798.
Bread, or beer, 196; war, digestibility of, 120; war, ergotism from, 196.
Breast, carcinoma of, Röntgen therapy in postoperative treatment of, 809; carcinoma of, with extensive resection, 250; carcinoma of, *x*-ray in, 17; feeding, 244, 893; tumors of, galvanocautery knife for excision of, for microscopic diagnosis, 421.
Brewer, I. W., house infection, a potent source of tuberculosis, 523.

Phenolsulphonephthalein excretion in infancy and childhood, 502.
Phenoltetrachlorphthalein test of liver function, 795.
Photoangiophobia, 570.
Physical examinations for life insurance, carelessness in, 581; versus psychical in psychiatry, 1053.
Physician and medical society, civic responsibility of, 718; and Weather Bureau, 585; employment of, by agent of corporation, 485; infections of fingers and hands of, 1107; nondrug giving, licensing of, 150; relation of, to public health administra-

tion, 495; services of, liability of corporation for, 109; the versatile, 489
Picric acid and benzidin stain, 787, acid as an antiseptic, 622.
Pictures, motion, a peril of, 529.
Pigmentation, universal, 976.
Pineal gland, 331; gland, function of, 446.
Pituitary extract, 843; extract, action of in asthma, 454; extract causing rupture of uterus, 160; extract, effect of, on salivary secretion, 703; extract, observations on the use of, 607; extract, value of, in obstetrics and gynecology, 722; gland in diabetes mellitus and other endocrin disorders, 834; gland, tumor of, 172.
Pituitrin, effect of, on lactation, 938.
Placenta, adherent, delivery of, 377.
Plaguc, rodent, relation of, to human infection, 973.
Plasma and blood volume, determination of, 789.
Pleura, effusion in, laryngotracheal sign in, 111; open puncture of, 371; suppuration in, treated with irrigation drainage, 119.
"Plexalgia," a disease of war, 30.
Plumbism, 757.
Pneumobacillus of Friedlander, sepsis from, 983.
Pneumococcus, arthritis from, 534; and ethylhydrocuprein, 614; infection of throat with, 433.
Pneumonia, broncho, ether, camphor, and guaiacol in treatment of, 550; digitalis in large doses in treatment of, 466; ethylhydrocuprein in, 160; foreign body, 540; in children, 541; lobar, 284; lobar, a rational method of treating, 345; respiratory mechanism in, 932; sitting posture in treatment of, 68; specific prophylaxis and treatment of, 748; treatment of, 214; treatment of chemotherapy, 1068; treatment of, with ethylhydrocuprein, 937.
Pneumothorax, an unappreciated form of, 719; artificial, 932; artificial, exudates in, 601; artificial in treatment of pulmonary tuberculosis, 453, 1019; spontaneous non-tuberculous, 81; therapeutic, in pulmonary tuberculosis, 719; pyo-, spontaneous, 991.
Poisoning, acute benzol, chemical diagnosis of, 1108; lead, industrial, 876.
Polioencephalitis, pontine, 902.
Poliomyelitis, foot deformities from, 533; Landry's paralysis and, 436; prevention and treatment of deformities in, 439; treatment of, 76.
Poisoning, hypnotic drug, 149.
Poisons, cardiovascular, decomposition food products as, 620.
Pollentherapy in hay fever, 157.
Polyclinic Hospital, a disclaimer from, 72.
Polyneuritis of motor type, 810; of rubber vulcanizers, 153.
Pontocerebellar tumor, 897.
Pool, E. H., breaking glass tubes containing suture material, 320.
Porter, W. E., comparative mortality experience among abstainers and non-abstainers from alcohol, 732.
Post-mortem reflexes, 621.
Potassium iodide elimination of, in urine, 621; permanganate in examination of cerebrospinal fluid, 972.
Practice, medical, illegal, penalty for, 403; medical, act of Oklahoma held valid, 485.
Practising without license, 962.
Pregnancy, ampullar, 628; and pulmonary tuberculosis, 719; and sterilization, combined operation for the interruption of, 721; clinic and midwife, a comparison, 971; ectopic, 419; hyperemesis of, acid intoxication of, 755; ovariotomy in, 714; plasma and blood volume in, 453; pyelonephritis in, 421; serum studied in, 544; surgical operations during, 722.
Prostate gland, calculi of, 454; hypertrophy, incipient of, 756; in youth, 383; prostatisme sans, 1103; suppuration in, internal aspects of, 101.
Prostatectomy, caudal anesthesia for, 891; mistakes and failures, 667; suprapubic, anesthesia for, 887; transvesical, 666.
Prostatic, when fit for operative procedure, 891.
Prostatisme sans prostate, 1103.
Prosthesis, American limb, and the war, 323.
Protein intake, influence of, on excretion of acetone bodies in urine in diabetes, 806.
Protozoa, intestinal, of man, 1105.
Pruritus, treatment of, 493; vulvae, 680.
Psoriasis, para, 971.
Psychiatry and neurology, exact and inexact methods in, 168; and war, 205; physical versus psychical in, 1053.
Psychoanalysis, use of term, 477.
Psychology, clinical, in its relation to the school and to social medicine, 861.
Psychopathic hospital, value of, 720; laboratory, 1069; subjects, faradic stimulation in, 329.
Psychopathies, alcoholic, 1096.
Psychosis associated with cerebral arteriosclerosis, 1003; of renal type, symptomatic, 868.
Public and profession, 766.
Public health school, 929.
Puerperal infection and septic abortion, treatment of, 765.
Puerperium, the, 1064; creatin and creatin excretion during, 885.
Pulmonary tuberculosis, a new sign in, 495; and pregnancy, 719; apical, percussion in diagnosis of, 537; appendicitis as complication of, 588; artificial pneumothorax in treatment of, 453; cavities in, prognostic significance of, 75; early diagnosis of, 474; early movement of diaphragm in, 332; errors in diagnosis of, 842; hardening in, 525; hemoptysis in, 805; immunized milk as a prophylactic and remedy, 917; Kroenig's isthmus in, 1102; lactic acid treatment of, 877; pancreatic ferment in, 710; pneumothorax, artificial in, 453, 719, 1019; Röntgen therapy in, 809; salt as preventive of sweating in, 759; therapeutic pneumothorax in, 719.
Pulse, rapidity of the, 936; venous, auscultation of, 518.
Purpura, 30.
Pyelitis in infancy and childhood, 803.
Pyelonephritis in pregnancy, 421.
Pylephlebitis complicating appendicitis, 151.
Pylorospasm and rumination, 34.
Pylorus, exclusion of, by string method, 589; stenosis and spasm of, differential diagnosis of, 542, 543.
Pyopneumothorax, spontaneous, complicated by hydro- or pyopneumopericardium, 991, 1030.
Pyorrhea, alveodental, and endameba buccalis, 534; alveolaris, 330; alveolaris, emetine in, 242; alveolaris, fatal case of, 670; alveolaris, mouth wash, 680.

Q

Quarantine of the home as practised by Pennsylvania department of health, 719.
Questions, hypothetical, 1094.
Quinine after rectal operations, 786; derivative, new, as an oxytocic, 848.
Quinsy, fatal hemorrhage as results of, 966.

R

Radiant energy, 1020.
Radioactive elements in medicine, 1031.
Radium, action of, in cancers of pelvic organs, 1019; and lymphangioma, 215; cure of *x*-ray epithelioma, 41; in carcinoma of cervix uteri and vagina, 1019; in gynecology, 251; in uterine carcinoma, 118; internal therapeutics of, 137; rationale of, in treatment of malignant tumors, 631; the effect of intravenous injections of, on a persistent positive Wassermann reaction, 610; treatment for carcinoma of breast, 630; treatment for primary cancer of the vagina, 630; treatment for rhinoscleroma, 630; treatment of cancer by, in conjunction with surgery, 765; treatment of cancer of buccal cavity by, 937; treatment of epithelioma of nose, 630; *x*-ray keratoses cured by, 590.
Raynaud's disease and angina pectoris, 415; disease, calcium lactate in, 382; syndrome, 833.
Recklinghausen's disease, 1098.
Rectal constipation, 595; operations, 961.
Rectum, carcinoma of, combined operation for, 40; operations on, quinine after, 786.
Reflex disturbances, physical treatment of, 809.
Refraction, in school children, 577.
Remedies, proprietary, German substitutes for, 246.
Remer, J., the *x*-ray treatment of ringworm of the scalp, 217.
Renal-cardiovascular disease (arteriosclerosis), 593.
Renal disease, chronic, management of, 1026; function, creatinine as test for, 755; infections, diagnosis of, 894; mechanics of, 894.
Respiration, dead space in, 195; deep, posture and arm movements in, 534; experimental infections and, 447; insufficiency of, and tuberculosis, 270.
Respiratory disease as factor in infant mortality, 1110.
Retina, detachment of, new operative procedure for, 931; sclerotrephine operation for, 934.
Rheumatic affections, chronic, external treatment of, 714.
Rheumatism, acute, magnesium sulphate in, 130; and gout, 22; and the skin, 815; colloidal sulphur in, 570.
Rhinitis, atrophic, 1018.
Rhinophyma, its etiology, pathology and treatment, 668.
Rhinoscleroma, treated by radium, 630.
Rice, W. F., some difficulties in the diagnosis of general paralysis of the insane, 107.
Rice diet in eczema, 441.
Rickets, Röentgenographic appearances in, 1104; sex distribution in, 150.
Rideal, S., the testing of disinfectants, 410.
Riha, W. W., tuberculosis in children, 229.
Ringworm of scalp, vaccine treatment of, 167; of scalp, *x*-ray treatment of, 217.

Roosevelt Hospital, operating room technique at, 591.
Rosenberg, J., immunized milk in the prophylaxis and treatment of typhoid fever, 695; the value of immunized milk as a prophylactic and remedy for tuberculosis, 917.
Rucker, S. T., treatment of opium or morphine addiction, 746.
Rueck, G. A., staphylococcus septicemia complicated by subpectoral abscess, 105.
Rumination and pylorospasm, 34.

S

Saline solution, hypertonic, in gynecology, 935, 1097.
Saliva, effect of pituitary extract upon, 703.
Salt as preventive of sweating, 759.
Salvarsan, and its substitutes, 200; and mercury, results of, in eighteen cases of primary syphilis, 920; arsenical keratosis following injections of, 800; fatalities from, 496, 580; for schistosomiasis, 944; galyl a substitute for, 668; limitations of, in syphilis, 623; neo-, in malaria, tertian, 1107; therapeutic effect in experimental trypanosomiasis, 720; treatment of syphilis with it alone, 580.
Sandy, W. C., pneumococcic infection of the throat, 433.
Sanitary engineer in public health work, 844.
Sarcoid, Boeck's, 937.
Sarcoma, chicken, complement fixation in, 403; melanotic, 853.
Satterthwaite, T. E., the prognosis in cardiovascular diseases, 857.
Savini, C., the excision of the fistulous tract in the treatment of fistula in ano, 646.
Scalp, ringworm of, vaccine treatment of, 167; ringworm of, *x*-ray treatment of, 217.
Scarlet fever, ethylhydrocuprein in, 848; serotherapy of, 713; suprarenal impairment in, 473; treated with fresh blood from convalescent patients, 335.
Schapps, J. C., amputation of the great toe, with remarks on the muscular physiology of the lower extremity, 516.
Schick test, 505, 576, 756; test, pseudoreactions with, 152; test, practical value of, 803.
Schistosomiasis, salvarsan for, 944.
Schlapp, M. G., the clearing house for mental defectives, 299.
School and social medicine, clinical psychology in its relation to, 861.
Schools, open-air, medical aspects of, 844.
Science and war, 797.
Sclerema neonatorum, 835.
Sclerosis, multiple, unusual case of, 807.
Sclerotrephine operation for detached retina, 934.
Scoliosis, rigid, treatment of, 535.
Scopolamine and morphine amnesia in obstetrics, 578, 718; present status of, 721.
Scorbutus, infantile, 948.
Scrofula, 848.
Scurvy, infantile, 578.

Secor, W. L., an improved and simplified technique for autoserotherapy, 108.
Secretin in therapeutics, 506.
Selection, medical, factors determining, 79.
Semilunar bone, dislocation of, 1103
Sepsis, anaerobe, 975; colloidal therapy in, 722; from pneumobacillus of Friedlander, case of, 983; recrudescence of, in healed wounds, 710.
Septicemia, diplococcus, and hemopoietic organs, 372; in infancy, 530; staphylococcus, 105.
Sera, observations on, 292.
Serobacterins and vaccines, typhoid, immunity following use of, 934.
Serology of tetanus subjects, 848.
Serotherapy of scarlet fever, 713.
Serum, blood, refractometric determinations, 797; study of, in pregnancy, 544.
Services, medical, see physician.
Sesamoids of the flexor brevis hallucis, 884.
Sex determination, age of parents a factor, 759.
Sexsmith, G. H., bone grafting and arthroplasty, 775; the diagnostic value of Bence-Jones albumin in the early stages of a case of multiple myeloma, 600.
Sexual diseases and war, 29; power, impairment and loss of, in acromegaly, 829.
Shaw, T., the causation and treatment of pellagra, 275.
Shock, suprarenal gland in, 40.
Shoulder injuries, the common, 576.
Sickness and premature death, Economic waste of, 1104; insurance, 1104.
Sight, weak, treatment of unilateral, 1107.
Sigmoid, abnormality of, 675.
Silver, colloidal, therapeutic use of, 800.

Trench fever, so-called, 1067; frostbite, 622.
Trichinosis simulating frontal sinusitis, 710.
Trichocephalus dispar infection, 318.
Trudeau, E. L., resolutions on the death of, 969.
Trypanosomes, 159, 203, 241, 244.
Trypanosomiasis, experimental, comparative therapeutic effect of mercury and salvarsan, 720.
Tubercle bacillus, in circulating blood, 207, 814; bacillus, in gastric contents, 152; bacillus, virulence of strains of, 208.
Tuberculin as an aid in surgical tuberculosis, 1049; attempted suicide with, 455; tests in children of Colorado, 36; use of, by mouth, 806.
Tuberculosis, anatomicopathological questions in, 588; and bovine infection, 250; and department stores, 306; and house infection, 523; and housing, 362; and lymphoid marrow, 1019; and new growths of prostatic urethra, 755; associations as health educators, 368; autopsy, war, and, 749; bovine, danger of, 338; care of child with, 338; cases not in State sanatoria, 842; cervical gland, 76; decreasing mortality from, 497; dependent upon respiratory insufficiency of upper air tract, 270; gastric symptoms in, 827; general, including skin, in a child, 541; gunshot wounds of the lung and, 713; heart and blood vessels in, 893; immunity to, 207; immunity against, through drinking milk, 787; in childhood, what constitutes? 842; in children, 229; in children, pathology of, 337; in children, transmission of, 337; infection of, retained in books, 203; laryngeal, 452; movement, responsibility of State in, 349; of patella, 795; miliary, of liver, 1032; personal equation in treatment of, 562, 583; present knowledge of, 534; pulmonary, see pulmonary tuberculosis; stigmata of, 1037; surgical, tuberculin in, 1049; the sustained failure in the problem of, 657; water in prevention and cure of, 173.
Tubes, glass, breaking, 320.
Tumor of right occipital lobe, 807; cerebellar, localization of, 756.
Turpentine as a hemostatic, 331.
Tweddell, F., eczema and the Bulkley rice diet, 441.
Typhoid, and dysentery infection, mixed, 1068; bacillus and paratyphoid bacillus isolation of, from feces, 413; carrier, 27; fever, 246; fever, acute cholecystitis complicating, 422; fever, agglutination reactions after inoculation against, 579; fever, antityphoid inoculations, influence of, on cases in German army, 758; fever, autopsy finds in, 615; fever, disinfection of stools in, 805; fever, esophageal stenosis following, 235; fever, experiences in the treatment of, by stock typhoid vaccine, 711; fever, from unpasteurized milk supply, 973; fever, high calory diet in, 234; fever immunes, 888; fever, immunization and latent malaria, 69; fever, immunized milk in the prophylaxis and treatment of, 695; fever, immunotherapy and serotherapy of, 332; fever in children, 754; fever, in children, intestinal hemorrhage in, 356; fever, in East Prussia, 288; fever, in inoculated subjects, diagnosis in, 286; fever, inoculation of nurses against, 493; fever, liver abscess in, 422; fever, lumbar puncture for the endocranial symptoms of, 661; fever, outbreak of, and its cause, 1028; fever, para-, 964, 1021; fever, para-, clinical characteristics of, 845; fever, paralysis after, 714; fever, polymorphonuclear leucocytosis in, 897; fever, specific treatment of, 120; fever, strychnine, iodine, and arsenic in, 130; fever, sulphur in treatment of, 298; fever, treatment of, with typhoid vaccine administered intravenously, 648; fever, treatment with Besredka's vaccine, 580; fever vaccination, therapeutic in, 800; fever, vaccine, 796; fever, vaccine treatment of, 550; fever, vaccines and serobacterins, immunity following use of, 934; vaccine, stock, in treatment of typhoid fever, 711.
Typhus fever, 892, 941; fever, and von Prowazek, 21; fever, clinical aspects of, 1067; fever, epidemiology of, 286; fever, etiology of, 536; fever, form of, endemic in New York, 914; fever, Fraenkel's histological test for, 303; fever, mortalities, 406; fever, on the conjectural exciting cause of, 714; fever, suspected, 280.

U

Ulcer, gastric and duodenal, from standpoint of internist, 893; gastric and duodenal, surgery of, 1085; gastric, relation of, to gastric cancer, 893; gastric, resulting in gastric cancer, 709; gastric and duodenal, notes on, 708; gastric and duodenal, chronic, diagnosis of, 843; gastric, and duodenal, acute perforation of, 619.
Ulnar nerve, neuroma of, 755.
Uncinariasis, chenopodium in treatment of, 885.
Urea, blood, and blood cryoscopy, 973; excretion, 43.
Uremia, 800.
Ureter, calculus of, 846; calculus of, *x*-ray diagnosis of, 1079; cystoscopic methods in stricture and calculus of, 41; stone of, 28; upper, non-calculus obstruction of, 460.
Urethra, female, primary cancer of, 418; posterior, growths in destroyed by high frequency current, 973; prostatic, new growths of, in relation to tuberculosis, 755.
Urinary calculi, formation of, 577; tract, in women, laboratory diagnosis of chronic infections of, 421; tract, involvement of, from focal infection in children, 38.
Urine, elimination of potassium iodide in, 621; hemolytic action of, 888; sulphates in, volumetric determination of, 398.
Urogenital tract in routine examination, 851.
Uterus, arteriosclerosis of vessels of, 850; carcinoma of, 420; carcinoma of, radium in, 118; complete rupture of, 244; fibroids and hemorrhage of, *x*-ray treatment of, 420; fibroids of, treated by thiosinamine, 382; inoperable carcinoma of, application of heat in, 83; inversion of, in multipara, 413; prolapse of, 418; removal of, in menstrual disorders, 676; rupture of, from use of pituitary extract, 160; sacral suspension of, 980; ubiquitous, 323.

V

Vaccination and superinfection, 489; typhoid, 800; unsuccessful, activated by injection of diphtheria antitoxin, 372.
Vaccine, therapy, blood counts in relation to, 179, 207; therapy in a general hospital, 210; treatment of Hodgkin's disease, 757; treatment of ringworm of scalp, 167; treatment of typhoid fever, 550; typhoid, 796; virus and tetanus, 447; virus, artificial cultivation of, 669; virus free from bacterial contamination, 902.
Vaccines and serobacterins, typhoid, immunity following use of, 934; autogenous, in bronchitis and asthma, 891; combined, Castellani's, 321; in diseases of nose, throat, and ear, 157, 164; in eczema, 329; in gonorrhea, 1105; in hay fever, 270.
Vagina, absent, surgical treatment for, 766.
Vagotonia, 77; paroxysmal, treatment of, 550.
Vein, rupture of, 291.
Venereal buboes, *x*-ray treatment of, 1022; disease and occupations, 1104; disease clinics, 1065.
Venezuela, tropical diseases of, 251.
Ventricle, fibrillation of, and chloroform syncope, 370.
Verneuil, luetic bursopathy of, 116.
Veronal-bromine synthetics, 537.
Verumontanitis, 667.
Vineburg, H. N., the advantage of Kelly's method of cystoscopy in women, 269.
Viscera, transposition of, in an infant, 503.
Vision, weakened, in soldiers, 414.
Vitamines and accessory nutrient substances, 976.
Voice sign in congenital syphilis, 795.
Vomiting, of infants, treatment of, 550; in gastroenteric infections, 405.
Von Prowazek and typhus fever, 21.
Von Recklinghausen's disease, 253.
Vulvovaginitis, gonococcal, treatment of, 243.

W

Walker, J. T. A., the testing of disinfectants, 410.
Walsh, W. S., the intelligent treatment of diseases of the skin, 698.
Walther, H. W. E., treatment of acute epididymitis by aspiratory puncture, 567.
War and anthropology, 661; and heart disease, 77; and insanity, 703; and medical education of women, 797; and psychiatry, 205; and sexual diseases, 29; autopsy, and tuberculosis, 749; dermatoses, 29; experience with infectious diseases, 1068; science and, 797; zone, observations in the, 943.
Warfare, naval, casualties of, 41; spinal injuries of, 1106.
Warning, a, 750.
Wassermann reaction, 62, 1065; reaction, as reported from different laboratories, 534; reaction, comparative results of, 166; reaction, persistent positive, the effect of intravenous injections of radium on, 610; reaction, pseudo-positive in uremia and intestinal toxemia, 166; value of, 527.
Water, drinking, 74; drinking, sterilization of, for soldiers, 836; drinking, zinc in, 1021; in prevention and cure of tuberculosis, 173.
Weather Bureau and physicians, 585.
Weight, excessive, and diminished longevity, 289; reduction, 709.
Weil's disease, etiology of, 1108
Wells, F. C., conservation work as applied to life insurance, 1040.
Wendkos, S., diagnosis and treatment of gastric neurosis, 564.
Whitman, R., operative therapeutics as illustrated by a hospital service, 143.
Whooping cough, 975.
Wildman, H. V., mental defectives, their importance, 1093.
Williams, E. H., the peace and war footing of alcohol, 226.
Wilson's disease, 252.
Wise, F., idiopathic hemorrhagic multiple sarcoma of the skin (Kaposi) with special reference to early diagnosis, 513.
Women in the medical profession, 951; war and medical education of, 797.
Wood, F. C., a review of the advances in our knowledge and treatment of cancer in the last thirty years, 1.
Woodbury, N. S., cerebellar symptomatology, 396

Wounds, continuous irrigation of, 203; due to shell fragments, treatment of, 160; gunshot, drainage of, 847; gunshot, of head, 758; gunshot, treated by excision and suture, 536; infected, antiseptic powder for, 680; infection of, 73; infection of, and their treatment, 1020; infection of, relation of dressings to, 371; infection of, treatment of, by antiseptics, 1106; in war, treatment of, 331; irrigation of, 846; local sepsis in, 1067; projectile excision treatment of, 159; projectile, of head, 796; septic, bacteriology of, 668; septic ionization treatment of, 203; septic treated by electrolytic bath, 669; septic, treatment of, 758; suppurating, succus allii in control of, 622; surface of large, treatment of, 371; treated by means of cell proliferants, 407; treatment of, by garlic juice, 1011; treatment of, new form, 758

X

X-rays and radium treatment for carcinoma of breast, 630; and radium treatment for primary cancer of the vagina, 630; cardiac anatomy and pathology, 894; Coolidge tube for, 288; epithelioma curable by radium, 41; filtered, in skin diseases, 1022; hard, for deep *x*-ray therapy, 420; in carcinoma of breast, 17; in diagnosis of kidney lesions, 851; *x*-rays, in diagnosis of ureteral calculus, 1079; in frostbite, 545; in fungating epithelioma, 846; in exophthalmic goiter, 391, 720; in intrathoracic lesions in children, 502; in menorrhagia, dysmenorrhea, and uterine myoma, 850; in non-malignant conditions, 1029; in ring-worm of scalp, 217; in treatment of venereal buboes, 1022; in uterine fibroids and uterine hemorrhage, 420; keratoses, cured by radium, 590; localization, 155; photographs as evidence, 403; photographs in rickets, 1104; studies after operations on stomach and intestines, 40; therapy in pulmonary tuberculosis, 809; therapy in postoperative treatment of cancer of breast, 809; treatment for malignant tumors, 631; tubes of Lilienfeld, Coolidge, and Zehnder, 455; value of, in diagnosis of gastrointestinal disturbances, 883.

Y

Yawning and tetanus, 111.
Yellow fever in laboratory animals, experimental, 923; fever mosquito, Finlay and, 361.
Yerba maté as substitute for tea and coffee, 414.

Z

Zinc in potable water, 1021
